# PROJECT NO. 7 COMMITTEE REPORT

C. L. Motl, Chairman, Maintenance Engineer, Minnesota Department of Highways

#### SYNOPSIS

This report, covering the work performed by various states on this research project, is essentially a continuation report. It should, therefore, be considered as supplementing previous reports submitted in 1948 and 1949.

The objective of the project continues to be a search for the percentage loss of strength suffered by highways subjected to freezing and thawing action.

Data gathered so far continues to indicate that there is a loss of strength, even though the extent or percent of loss varies considerably between different test points. The strength of all types of soils so far tested appears to be affected adversely by freezing and thawing action.

The following states have taken part in conducting tests during the year 1950: Iowa, Michigan, Minnesota, New York, North Dakota, and Ohio.

In this report material submitted by the contributing States is included in its entirety; and because of the interesting comments and the detailed information furnished, these reports merit careful reading and attention on the part of those interested in this subject. A few brief comments on the report submitted by each state might be helpful in directing your interest to the various reports.

In the report submitted by Iowa, it will be noted that testing was confined to a limited number of points, but the scope of tests includes not only plate bearings but also instrument testing with the North Dakota cone bearing machine and the Iowa subgrade resistance machine. Because this committee has included in its program a search for possible correlation of plate-bearing values with various instrument-testing values, the Iowa report is of special interest. The Iowa plate-bearing tests show loss in strength of load-carrying

capacity, but a correlation between plate-bearing tests and instrument tests has so far been inconclusive.

The Michigan report discloses that tests conducted by this state include three types of instruments but no plate-bearing tests. instruments used were the ring shear, the North Dakota cone, and the Housel penetrometer. A comparison of bearing results secured in the spring and fall of the year discloses a grand-average loss of strength for each type of instrument used, but the results secured at individual test points are quite erratic, indicating that this type of instrument testing, when applied to soils as they are found in the field, is likely to be seriously affected or influenced by some minor special condition encountered in the soil at the test It would appear that except point. where rather fine-grained soils of uniform texture are encountered, this type of testing is too delicate to be reliable. The supporting data

furnished in the Michigan report, together with the indicated conclusions reached, is a substantial contribution to the objectives of the research project. This report should also be of special interest to soils engineers.

The Minnesota report covers the results secured during the fourth consecutive year of testing. During previous years, testing in Minnesota was confined to 8 locations, while during the past year tests were made at 38 locations and 126 test points scattered thruout the state. results are similar to those secured in previous years - showing a substantial average loss of strength. Detailed information for each test point is given in tabulated form. During the past year no effort was made in Minnesota to carry on conebearing tests or to try to correlate them with field-bearing tests.

The New York report supplements information furnished by this state for previous reports. The work done in this state consists of both platebearing and North Dakota cone-bearing testing. The plate-bearing tests appear to indicate that some types of soils (lacustrine) suffer much greater loss in carrying capacity than do other types of soil known as alluvial or outwash, but all types of soil tested do show a loss in carrying capacity due to frost The cone-bearing tests action. quite generally disclose a loss in bearing value during the spring of the year, and the relationship between cone-bearing and plate-bearing tests is shown on the tabulations included in the report. Other interesting information relating to moisture, density, and subgrade characteristics is included in the tabulation.

North Dakota reports that it continued with its cone-bearing tests at the 10 locations where tests had been made in previous years. The report includes a considerable number of graphs illustrating the results

secured during the past year. Tests in North Dakota continued to disclose loss in carrying capacity of subgrades during the spring of the year at depths of 3, 9, 15, and 24 in. below the roadway structure. An examination of the data and graphs discloses a considerable fluctuation in percentage-loss values, but the overall average unquestionably discloses a general loss of strength. No effort has been made in North Dakota to conduct plate-bearing tests.

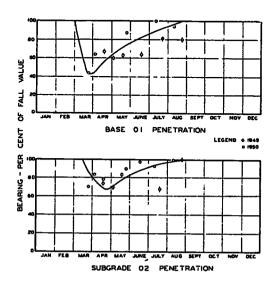

Ohio has made its first contribution to the work of the committee and has conducted field tests at a limited number of locations. Results of these tests shownoloss in carrying capacity of the highway during the spring of the year as compared to the previous fall, but the report also points out that the particular highway tested had very little frost penetration during the previous winter because of mild weather. Of interest in this report, however, 1s the data secured on the bearing value of the road structure at each of the four levels tested: on the surface, on the base, on the sub-base, and on the sub-grade. Since it is reported that the sub-structure elements of the road were not frozen during the previous winter, no conclusions can be made as to whether this particular road might or might not have been affected by frost action.

In concluding the preliminary comments on test results reported by the various states, we wish to point out that it is not the objective of the committee to determine soil-bearing values which might be used for road design purposes, since all of the factors that may affect the true carrying capacity of soils have not been evaluated, e.g., load repetition and moisture content. The bearing values recorded by either the plate method or the instrument methods were used to provide information on the relationship between spring carrying capacities and fall carrying capacities of roads. The data

should, therefore, not be presumed to establish basic values for soil carrying capacities.

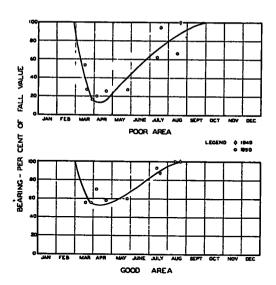

#### TOWA

Test Sites - Road Number Iowa 144. in Greene County, was chosen as the location for the field work, on this project. One section of this road extends southward from Grand Junction to Rippey and consists of a 6-in. gravel-clay stabilized base with an inverted penetration wearing surface. The other section of this road extends northward from Grand Junction to Dana, and consists of a 5-in. asphalt-emulsion-treated base of gravel aggregate, surfaced with an inverted-penetration wearing course. One test site on each of these roads was chosen for detailed plate-bearing tests at locations where the roadway showed evidence of good year-round servicability. At each of these locations, test sites in the opposite

Figure 2. Soil - Aggregate Base

traffic lane were later selected for the performance of quickie platebearing tests and these tests are noted as being in "good areas." One additional site on each of the two types of roadway was selected for the quickie tests in areas where incipient failure was in evidence, and these tests are noted as being in "poor areas".

Topographically speaking, the detailed tests were performed at the approximate center of level stretches of road at least 1/4-mi. long, where the centerline of the roadway was raised 4 to 5 ft. above the original ground line. This condition applies, of course, to the quickie tests performed in the good areas. The quickie tests in the poor areas were performed near the top of gentle grades, the test site being located near the end of the cut section through the low hills.

Since this entire area is located within the Mankato lobe of the Wisconsin glacial period, uniformity of material between the two sections of roadway and, as a matter of fact,

ROAD NO IOWA 144 NORTH OF GRAND JUNCTION
PLATE BEARING TEST
12° DIAM PLATE

Figure 3. Emulsion Treated Base

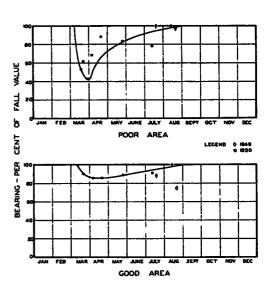

within a given section on either road, is poor. Generally speaking, the fill materials might be called a clay loam (P.R.A. classification A-2 to A-4-2) which varies locally to sandy loam or to gravelly clay loam.

Tests Performed - Approximately 50 detailed bearing tests have been completed on the two test sites. Each of these tests includes platebearing tests on the mat, on top of the base, and on the surface of the subgrade, together with North Dakota cone-bearing tests and tests with the Iowa Highway Commission subgrade Soil samples resistance machine. for laboratory tests and undisturbed soil specimens for density and moisture determinations are also obtained at various depths. Approximately 50 quickie-bearing tests have been performed at the above described sites, including some parallel-instrument tests.

Results of Tests - Results of the detailed plate-bearing tests on the

soil-aggregate base south of Grand Junction have been summarized graphically in Figure 1. The quickie tests on this road are shown in Figure Results of the detailed platebearing tests on the asphalt-emulsion base north of Grand Junction are shown in Figure 3, and the quickie tests on this road are shown in Figure 4. It will be noted that the curves for the tests on top of the base, including those for the quickie tests, have been based on a deflection of 0.1 in. due to the lack of capacity of our equipment to produce a deflection of 0.2 in. in every test attempted.

A thermocouple system for measurement of sub-surface soil temperatures was installed near the detailed bearing-test site south of Grand Junction, but an undetermined electrical or instrument defect rendered the results confusing. This installation has been dug up and checked and will be re-installed for use this next winter and spring.

## CONCLUSIONS

No exhaustive analysis of the data accumulated has thus far been attempted. Preliminary studies indicate that the correlation between the various instrument tests and the plate-bearing tests leaves much to be desired, although the present information is not thought sufficient to draw even tentative conclusions in this regard. It is hoped that the completion of another annual cycle of tests will help to clarify the situation.

The road north of Grand Junction. taken as a whole, is in very excellent condition. This is attributed, in part, to the tendency of the emulsion-treated base to retain a major portion of its strength through the thawing period, due to the stiffening of the asphalt during cool weather. The rather definite sag of the plate-bearing curves during the hot, summer months is thought to be the result of a weakening of the base caused by softening of the asphalt with increased temperature.

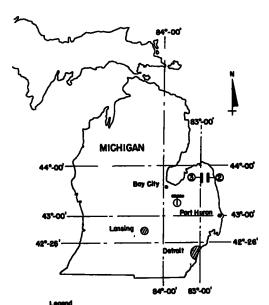

#### MICHIGAN

During the spring break-up period of 1950, the Michigan State Highway Department conducted the third in a series of field tests undertaken to study the effect of frost action on the load carrying capacity of roads. The first investigation by the Department was made in the spring of The second of the series followed in the late summer and early fall of that same year.

This report records the results of the third set of tests taken between April 6 and 28. 1950. tical test procedures were followed throughout in each series. For comparative purposes the road projects and test sites were the same as those investigated in the first and second series of tests. A general map, together with vicinity and detailed sketch maps, showing the locations of the test areas and precise locations of the test points are shown in the figures. The test holes in this report are numbered the same as corresponding test holes in the first and second reports, except that the figure 3, followed by a dash, precedes the original test hole number. This identifies the test and data as belonging to the third series of tests taken immediately adjacent to the points of the first and second series of tests.

General view pictures taken at the test sites on each project, supplement the detailed sketch maps. They show the local topography and general character of the roads under investigation.

In order to insure working in undisturbed materials, the exact points of the 1950 spring tests were located 18 in. to the right of the second series of test holes.

Figure 1. Map Showing Location of Michigan Field-Research Locations for Carrying Capacity of Frost Affected Roads

test pit openings were all 16 in. wide and 30 in. long (the length being parallel to the centerline of the road) and the maximum depths varied from 24 in. to 29 in. depths represent the lower floor of the pits, from which level one set of the various tests was conducted. The testing and sampling operations extended these pit depths 6 to 10 in. A complete set of tests was also run at a level 12 in. above these maximum depths as the pits were being developed. This upper level was normally the first clean exposure or contact with the natural subgrade soil after the road metal (and often

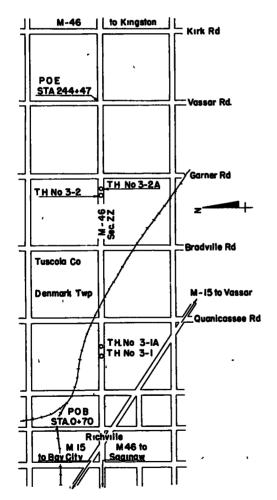

Figure 2. Map of Richville, Michigan, and Vicinity

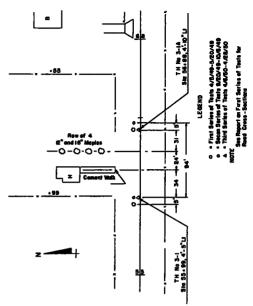

Figure 3. Map of Test Sites on M-46 Richville, E. for Third Series

a granular sub-base of imported material) had been removed.

In general, the tests were conducted at the pit elevations established in the earlier series.

A detailed drawing of the log and soil profile of each test hole is included in this report. The soil structure and textures should be similar to those found in the corresponding test holes of the first and second series of tests, being approximately 5 ft. from the former and 18 in. from the latter; however, disparities exist in some instances.

The methods of test adopted and used throughout the series to measure the relative bearing capacities of the subgrade soils are generally referred to as the indirect methods, or common denominator type of tests. These were namely, the Houselpenetrometer test, the ring-shear test and the North Dakota cone test. Independent soil density tests were also taken by the steel-cylinder core method.

Tests by these methods were taken in duplicate at each of the two

levels investigated in all test pits. The results obtained from these individual tests were tabulated and are shown in Tables I, II, and III.

Duplicate soil specimens were taken at most of the points tested. This operation was coincident with the Housel penetrometer test. From these specimens, the soil texture, field density, moisture, shear value, and, in some instances, the unconfined compression strength of the subgrade soils was determined. These data are recorded on Tables IV, V, VI, and VII.

A final tabulation sheet (Table VIII) shows a comparison between the bearing values obtained in the late summer and early fall of 1949 and those measured during the spring break-up period of 1950 by each of the three indirect methods of test. The amount of loss, or gain, in spring bearing-capacity is expressed as a percent of the corresponding fall value. The final figure at the bottom of Table VIII is the difference between the 1949 fall and 1950 spring bearing values averaged for the

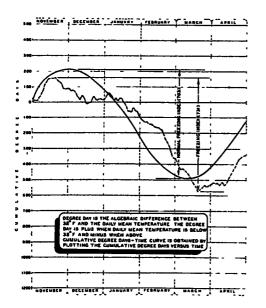

Figure 4. Determination of Freezing Index, Saginaw, 1949-50

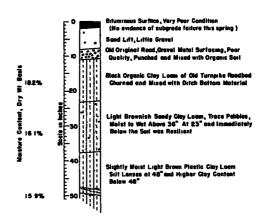

Figure 5. Bituminous Surface Failure Area Soil Profile

three projects and expressed as a percent of the average fall value as determined by each of the three individual methods of test.

According to soundings taken by the local road-maintenance crews, the frost penetration into the road subgrades during the winter of 1949-50 extended to depths of 15 to 20 in. The maximum depths were reached late in February and early in March. The winter weather up to February was considered mild for this climate. The weather following this period for a month or better was generally cold and wet with intermittent sharp, low freezing temperatures.

On two projects the frost extended into the road subgrades 25 to 33 in., as recorded between March 15 and 18, 1950. As late as March 22, 1950, the frost in the vicinity of Ubly and Ruth extended to depths of 15 to 20 in. in the fence lines; however, it was softening and in a "honey-comb" condition.

Between March 15 and 23, 1950, the period of maximum frost heaving, percise levels were taken at the Ruth and Ubly test sites on roadcenter lines. These levels were later plotted against the summer profiles, illustrating the extent of subgrade expansion due to frost. There was no pronounced differential frost heaving on any of the projects.

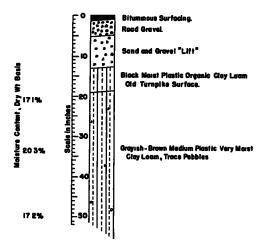

Figure 6. Non-Failure Area Soil
Profile

An exaggerated scale was used to plot the frost heaving, indicated by the dotted lines on the drawing.

Another observation made during the spring testing operations of 1950 was the resilient character of the subgrades in general and especially on the Richville E. M-46 project. This condition was more

obvious in the soils at the upper test level (directly beneath the road metal).

All of the spring tests recorded in this report were conducted under adverse weather conditions. pre-test soil auger-borings showed that the subgrades had thawed out completely before any tests were run, experiences in early-spring testing in northern climates suggest that a minimum soil and air-temperature standard be considered as a prerequisite before any "sensitive" tests, such as the present standard North Dakota cone tests are conducted. Pointing up the possible mitigating influence of low, but above freezing, temperatures on soil reactions, an instance was noted in connection with the digging of Test Pit No. 3-3 on the Ubly N. and S. The air temperature was 45 F.; a light, wet snow had fallen in the early forenoon and the temperature the night before had gone down to near freezing. The test pit was opened to a 12-in. depth and a set of tests were run; later the hole

was put down to a 24-in. depth for the next set of tests. The blacktop was 4-in. thick and the road gravel beneath was 6-in. thick resting on natural topsoil -- a dark, sandy loam. When first exposed the road gravel appeared dry and crumbly and the natural soil down to 19 in. was logged as quite dry. From 19 to 28 in. it was slightly moist. temperature of the soil in the upper part of the test pit was 42 F. and the lower part was 41 F., the air temperature remaining 45 F. In a short time, about half an hour, the side walls of the pit took on a glazed appearance and later became dripping Some of this moisture probably was condensation; however, after being exposed for about an hour the road gravel that earlier had appeared dry began to coze out from beneath the blacktop and flow down the sides of the pit. Laboratory tests later showed the soil between the 12- and 16-in. levels to contain 13.5 percent moisture and from the 24- to 28-in. levels 19.8 percent moisture. an assumption, but it appeared that the temperature of the soil at 41 and 42 F. immobilized the moisture which it contained until the warmer air released it. At any rate, the initial condition and structural characteristics of the exposed road gravel and underlying soil to the depth of the opened pit were rad1-

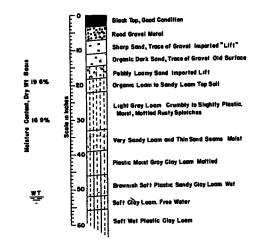

Figure 9. Non-Failure Area Soil
Profile

cally changed.

Regarding the system used in identifying the test holes and data therefrom, it is recalled that the original plan of test procedure specified that sites were to be selected which included both a "failed" and an adjacent "non-failed" area. The non-failure areas are identified throughout this report by the letter A, which follows the test hole numbers.

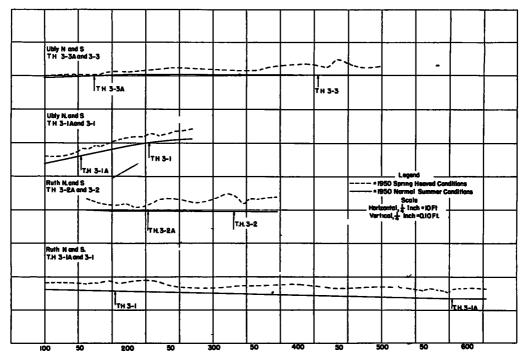

Figure 10. Comparison of Frost Heave Profiles for Third Series Michigan Tests

#### CONCLUSIONS

Through the medium of the indirect methods of test we can obtain a fairly reliable index of the structural capacity of any one soil texture within a foundation complex. However, when an attempt is made to comprehensively measure the passive resistance of the subgrade as a whole, certain limitations of the adopted test methods must be recognized. Irregularities and inconsistencies in the soil profile (a common occurrence in glaciated areas such as Michigan) are the major deterrents to the overall effectiveness of these methods.

When a subgrade is composed of a single soil texture or even a limited number of closely related textures and is generally free from pebbles, stones, incrustations, and waterbearing seams, an average of the bearing values of the components could be employed to reasonably calculate total carrying capacity.

However, when the subgrade is

composed of several textures varying in character, thickness, and water content, it becomes difficult to properly evaluate the resultant effect of the combination when subjected to stress. Frequently, the most critical elements or conditions in a subgrade are non-conformities of a nature most difficult to analyze. Even if they could be resolved physically and mathematically, their subtle influence on the soils immediately above and below and on the subgrade as a whole could not be gauged. This is especially true in the case of relatively thin waterbearing and soft or mushy seams which respond to the pumping action of traffic.

It is the writer's opinion that unless the combined reactions of all the soils and conditions that go into the make-up of a subgrade are measured while the subgrade is stressed in a repetitive manner, the actual carrying capacity of a road, especially one recently affected by frost, remains in doubt.

#### **MINNESOTA**

As a final phase of the investigation in Minnesota, it was decided to enlarge the field of testing to cover the state as a whole. The primary objective of the 1949-1950 survey was to explore, by full-scale load testing, the loss in load-carrying capacity of roads in the spring on a statewide basis and compare the results with those secured in previous years on a limited number of projects.

Test sections were selected to include the principal soil types in the state and variable thicknesses of flexible pavements. Figure 1 shows the approximate locations of the sections of road tested. On each test section, points were selected to represent average subgrade soil conditions. The subgrade soils ranged from sand to silty clays. A minimum of three test points were located on each project. Each point was located by stationing and by point on the pavement surface.

The first cycle of plate-bearing tests was made in September and October, 1949, to represent the approximate maximum load carrying capacity. A second cycle was made in April and May, 1950, as soon as the frost had left the subgrade. The plate bearing values obtained at this time were expressed as a percentage of the previous fall

All bearing values over 280 ps. are eatmated values obtained by extrapolation of the stress-strain curve Note

Loss of Road Strength and Recovery

values in determining the loss of load-carrying capacity.

Due to flood conditions in the northern part of the state, some test sections had to be deleted. On the 38 test sections, 126 and 1vidual tests were completed for both the fall and spring bearing values. Detailed information secured is shown in Table 1. An inspection of the data will disclose that all types of soils tested so far appear to suffer from frost action; and while the grand average of all losses recorded is 42 percent, the average for each soil type, as nearly as it can be identified, seems to vary only slightly from the grand average.

Another noticeable characteristic of the test results is that thickness of base in a road structure has no appreciable effect in reducing the percentage of strength loss, even though both the fall and spring carrying capacity of the road may be considerably improved because of the base construction. This can be

explained by the fact that the strength of a road structure starts with the subgrade soil, and the degree to which the subgrade soil is affected by frost action is reflected in the surface carrying capacity of the road itself.

In order to bring out the comparison between the data secured on the statewide testing program, as compared to the data accumulated from tests made at eight selected test points during the previous 3 yrs., Figures 2 and 3 are included in this report.

Figure 2 shows the average loss of load strength and recovery for the tests made in 1949, while Figure 3 shows the comparison of test results secured during the three years of 1947, 1948, and 1949. The average loss in strength was somewhat higher during these years than during 1950, but all of the information gathered in Minnesota so far indicates substantial strength losses following spring thawing and gradual recovery.

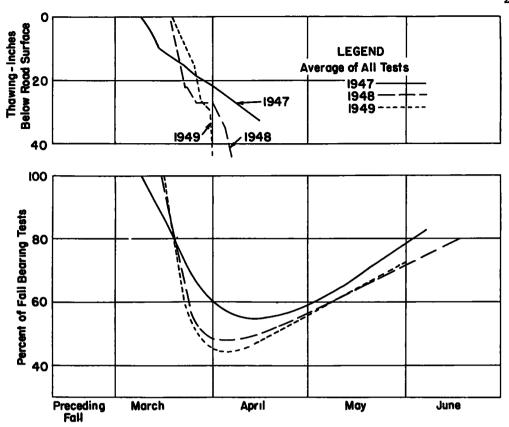

Figure 3. State of Minnesota - Dept. of Highways Comparison of Results of 1947 - 1948 and 1949 Tests

Figure 4.

### **NEW YORK**

As a continuation of the program of field strength measurements by the use of plate-bearing tests, the Pureau of Soil Mechanics instituted a program of measurements on various roads in Rensselaer and Washington Counties. Tests were performed at the same locations, both in the fall of 1949 and in the spring of 1950.

Most of the sites at which tests were performed were in cut sections. However, a few tests were run in areas of shallow fills. The pavement at these sites represented conditions of both good and poor performance. The subgrades included soils of glacial lacustrine, glacial till, and glacial outwash origin, and soils of alluvial origin.

The loading arrangement for the plate tests consisted of an I-beam supported beneath two 5 1/2-ton trucks. These trucks were loaded with additional weight (sand and gravel) to produce a reaction under the jack position of somewhat more than 15 tons. This arrangement is similar to that used during the 1948-1949 series.

In order to permit the testing of the wide range of soil types, the tests were run on the pavement surface only, using both the 6-in. and the 12-in. diameter plates. This simplification permitted tests at 30 locations. At all locations, tests were run using the 12-in. plates, with occasional tie-in tests using the 6-in. plates. Regular and quick tests were run with both plates. The load-bearing tests were supplemented by the North Dakota cone test on the fine grained soil subgrades.

A comparison of the test results obtained (see Table 1 and Fig. 1) shows that the load bearing capacity in the spring averages from 53 to 86 percent of the fall values for all soil types tested. For lacustrine soils, the spring values are approximately 55 percent of the fall values, showing the greatest loss of strength due to frost action. The till, aluvial, and outwash soils show a lesser loss of strength, averaging 70 to 75 percent of the fall value.

Because of the large numbers of variables that may influence the bearing capacity of soils, it is impossible to say that any one factor is more responsible than any other factor. An attempt has been made to relate a number of the variables; however, only the relationship between the total thickness of pavement and the plate loading at 0.1-in. deflection for glacial lacustrine and glacial till soils seems to indicate a definite pattern. A plot of these data is given in Figure 2. No definite correlation was found between plate load values and field moisture contents, field cone bearing values, subgrade density, or characteristics

TABLE 1
SUMMARY OF SPRING LOAD BEARING VALUES REPRESENTED
AS A PERCENTAGE OF THE FALL VALUES

	12-inch D at Defle	iam. Plate ction of	6-inch Diam. Plat at Deflection of						
Soil Type	0.10 nn.	0.20 in.	0.10 in.	0.20 in.					
Till Soils	65		69	79					
Lacustrine Soils	53	53	56	56					
Alluvial Soils	74	77	74	71					
Outwash Soils	86		72	72					

Note: These are average values for each soil type investigated.

Soil Series - Hudson Depositional Unit - Lacustrine

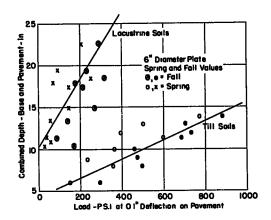

Figure 2.. Load P. S. I. vs Combined Depth of Base and Pavement.

of the individual subgrade soils.

As you will see by examining Tables 2 to 6 there was considerable variation in the field moisture content of the subgrade materials at the time of test. It is our belief that such variations could have a very large influence on the bearing value obtained. An evaluation of this factor, however, is not possible from the data we have on hand.

It may be that a comparison of the field data obtained by this series of tests with those from other areas may provide interesting correlations.

#### NORTH DAKOTA

For the period covered by this report, (July 1 - Aug. 31, 1950) tests were continued on the 10 permanent test-points selected in 1948: one test point for gravel surface, one for bituminous armor coat, three for cold-laid oil-mix mats, one for hot-mix bituminous resurface, and four for asphaltic-concrete wearing surfaces.

Bearing tests were made only with the North Dakota cone device and at 3-, 9-, 15-, and 24-in. depths in the subgrade. Other data taken includes soils analysis, temperature, and subgrade density and moisture content. (Cone bearing device principally intended for use in finegrain soils.)

From the data obtained in 1949, fall bearing values for each test point were established. These values were plotted as 100 percent on the 1950 graphs in this report. All other test values for bearing power were plotted as percentages of the fall values.

The former progress report terminated on July 1, 1949. The test data obtained after that date up to November 22, 1949, when frozen conditions suspended operations for the winter, have been added to the 1949 report graphs and included herein to complete the 1949 information. From July 1, 1949, to November 22, 1949,

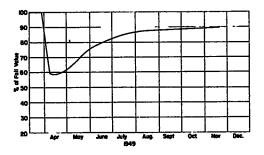

Figure 1. Average Bearings for All Tests at the 10 Test Points Bearing Tests with North Dakota Cone Device.

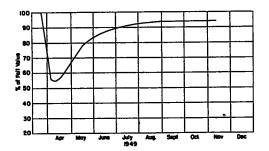

Figure 2. Average Bearing for the 10 Test Points at 3 in. Below Subgrade Surface Bearing Tests with North Dakota Cone Device.

48 complete tests were made. These results were plotted as continuations of the graphs contained in the progress report to July 1, 1949. Added to the work performed before July 1, the total number of tests made in 1949 was 115.

Figure 6 shows a curve representing the average bearings for all tests made in 1950 at the 10 test points, regardless of test depth. It establishes the general trend of the loss of load-carrying capacity when the subgrade is thawing, and the subsequent recovery. For 1950 it will be noted the curve shows a rapid recovery from May 10 to June 12 afterwhich a loss in bearing power occurred to July 5. Then recovery was resumed again up to the report date of August 31. ratic procedure was not anticipated and is not definitely accounted for. However, plausible reasons are offered and the matter discussed more in detail later in this report.

Figures 2 to 5, 1949, and 7 to 10, 1950, show the average bearings for all tests at the 10 test points at the respective depths of 3, 9, 15, and 24 in. below the subgrade surface.

The following observations have resulted in regard to the subgrade bearing tests with the North Dakota cone device:

1. All test points show a decline in bearing strength during the

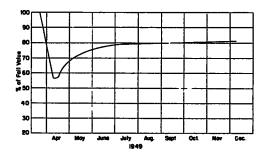

Figure 3. Average Bearing For the 10 Test Points at 9 in. Below Subgrade Surface Bearing Tests with North Dakota Cone Device.

spring thaw with a subsequent recovery thereafter.

- 2. Not all test points follow the same pattern of recovery.
- It was noted that the average recovery in subgrade bearing strength for all tests at the 10 test points did not reach 100 percent during the 1949 season. Figure 1 shows that when field work was suspended in the fall of 1949 the average recovery had only reached 90 percent of the previous fall value. This may have been due in part to selection the previous year of fall values that were too high. Such procedure could be the result of the lack of previous data and experience to establish sounder judgement in determining reasonable fall values.

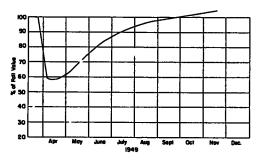

Figure 4. Average Bearings For the 10 Test Points at 15 in. Below Subgrade Surface Bearing Tests with North Dakota Cone Device.

Because of this probability, prior to the resumption of field work in the spring of 1950, the fall values obtained in 1949 were reviewed and adjusted to more suitably fit the average results obtained by the field tests. These adjusted fall values are shown numerically in Table 1 and may be compared with the 1948 fall values used in 1949, which are also shown in the same table.

One research party was started during April 1950. This was a later start than usual due to the abnormally cold spring which caused the frost to come out of the ground very slowly. For this reason one party could readily handle all the test points and keep up with the rate of frost recession.

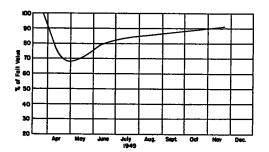

Figure 5. Average Bearings For the 10 Test Points at 24 in. Below Subgrade Surface Bearing Tests with North Dakota Cone Device.

The first test was made April 13 at 3 in. below the subgrade surface. The first test possible at the 24-in. depth after disappearance of frost was made April 26. There were 69 complete tests made between April 30, 1950, and August 31, 1950.

The results were plotted and are shown in this report by 1950 graphs, Figures 6 to 10. (Graphs for individual test points are not reproduced here.) As can be noted by studying the curves for all the test points and the averages for all tests at the 10 test points the results are found to be quite erratic for the 1950 season. We have been unable

TABLE 1
TABULATION OF FALL VALUES FOR 1949 AND 1950

Test		194	8 Fall	Value	:5	19	49 Fal	l Valu	es.
Poin	t Location		For 1	949			For	1950	
No.			Inch	es			Inc	hes	
		3	9	15	24	3	9	15	24
1	US 83 Sterling South	827	398	282	239	788	378	209	224
2	N.D. 3 North of Steele	1087	309	1077	307	718	537	344	289
3	N.D. 13 East of Edgeley	1332	465	596	1352	1272	455	764	1162
4	US 52 Southeast of Sawyer	391	327	298	381	553	240	250	255

6	US 10 West of Sterling	1880	1183	852	706	1047	536	478	542
7	US 10 East of Sterling	795	895	419	515	900	400	588	714
8	US 10 East of Menoken	807	288	1040	850	754	366	1015	357
9	US 10 West of Jamestown	1154	803	758	667	1214	856	814	660
10	US 52 Southeast of Donnybrook	1037	779	473	361	874	450	462	348

to definitely account for these variable results, but some of the causes may have resulted from the abnormal climatological conditions this season. Also, it was necessary to make personnel changes in the field party during the season. However, their work was spot checked by more experienced men to assure utmost accuracy in the field results.

Another important reason probably pertaining to erratic results is the fact that recent tests are now falling some distance farther down the road than the actual location of the original test points. This procedure is considered necessary in order that each new test will occur at an

undisturbed location. In this manner some undetected changes in soil composition or presence of other unknown factors could affect the uniformity of bearing values obtained. To minimize the effect of this possibility, tests were finally made during 1950 on the opposite side of the centerline than formerly and as near the original location as possible. However, this procedure has not appeared to improve or affect the uniformity of results to any appreciable extent up to the time of this report.

The month of April was the coldest April since records began for this state. Unusually heavy snow covered the ground during the first half of

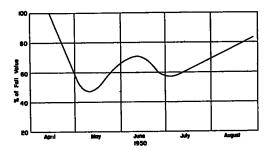

Figure 6. Average Bearings For All Tests at the 10 Test Points Bearing Tests with North Dakota Cone Device.

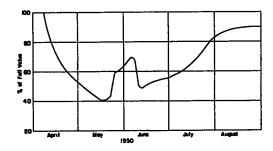

Figure 7. Average Bearing for the 10 Test Points at 3 in. Below Subgrade Surface Bearing Tests with North Dakota Cone Device.

the month. Consequently, the thaw period was retarded and not much testing could be accomplished in April.

The outstanding feature of May weather was its continuation of one of the most backward seasons ever experienced in North Dakota. record of snowfall was established for the month. The Weather Bureau records show an average snowfall for the state of 8.8 in. which was more than twice the previous all-time high of 4.0 in. set in 1905 for May. This compares with a normal snowfall of 1/2 in. for the month of May. condition no doubt largely accounts tor the low average subgrade bearing around May 10, which equals 47 percent of the previous fall value for the average of all test points. comparison, the spring value average in 1949 for all 10 test points was 58 percent of the previous fall value.

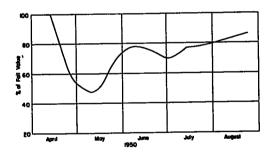

Figure 8. Average Bearing For 10 Test Points at 3 in. Below Subgrade Surface Bearing Tests with North Dakota Cone Device.

June was a warm and dry month, and during this period the subgrade at all the test points showed partial recovery. On June 24 and 25 rain was general throughout the state. This moisture seemed to affect the subgrade considerably as the average bearings dropped substantially thereafter.

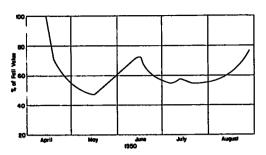

Figure 9. Average Bearing for 10 Test Points at 15 in. Below Subgrade Surface Bearing Tests with North Dakota Cone Device.

ally improved and the recovery of subgrade bearing power resumed during that month.

August weather was similar to that of July and subgrade bearings continued to improve.

In conclusion, the 1950 variable results appear somewhat disappointing as more uniform results were anticipated. The results reported are those actually obtained without discounting or culling the extreme values. For utmost accuracy, tests were often repeated as many as four times before a single reading was finally accepted and recorded as representative of the conditions at the time of the test.

After plotting the results on the curve sheets the variations are graphically apparent. The curves shown are the actual averages for

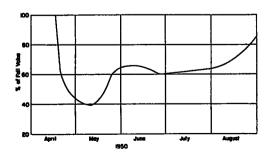

Figure 10. Average Bearings for 10 Test Points at 24 in. Below Subgrade Surface Bearing Tests with North Dakota Cone Device.

the bearings shown and plotted. For this reason the curves are not as uniform as might be the case. No doubt more uniformity in the curves could be obtained by studying the general trends of the data and then by redrawing curves representative of those trends from which extreme values have been culled or discounted. This point is casually mentioned for consideration in case such procedure appears practical.

Without question, however, the

## OHIO

The plate-bearing tests in Ohio were made on a road selected as typ1 cal of modern, heavy-duty, flexible
pavements on US 36, Mileage Station
22.62, Delaware County and the pavement section included: 4 in. hotmixed bituminous concrete; 8 in.
waterbound macadam; 10 1/2 in. classified embankment material.

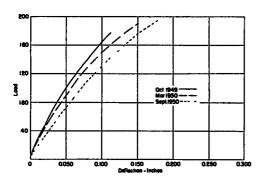

Figure 1, Average Tests on Surface.

The plate bearing tests were made in accordance with the procedure outlined by the committee, using a 12-in. plate. The charts show the average load-deflection curves obtained on each layer of pavement in three series of tests made on the dates shown. There was little difference between the fall and spring tests and consequently a percentage load-season curve based on loads at 0.2 in. was not attempted. The

1950 work re-established the 1949 result that a large loss of subgrade bearing power, amounting to approximately 50 percent of the previous fall value, occurs during the spring thaw period. It is sincerely hoped that as the research work progresses, more skill in testing will be developed and that additional valuable and reliable information pertaining to the project will be compiled for use by this state and the committee.

1949-1950 winter in this area was very mild, and it is doubtful if frost penetration ever extended to the top of the subbase and rarely to the depth of the top of the macadam.

The average temperatures recorded at the time tests were made were:

	Average Temperatures											
Item	Oct. '49	Mar.'50	Sept. '50									
Air	52 F	63 F.	80 F.									
Batumanous Concrete	56	48	76									
Macadam	58	54	74									
Subbase	60	49	75									
Subgrade	62	AR	79									

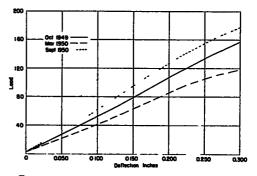

Figure 2, Average Tests on Macadam.

Tests made in this same location with the North Dakota cone bearing equipment were inadequate and no results are reported. The subgrade contained considerable granular material. Limitations on the amount of subgrade that can be exposed for

testing on a completed pavement result in an insufficient number of readings to obtain a comparison.

The subgrade soil consists of

H.R.B. Class A-6 (6) having a liquid limit of approximately 28 and a plasticity index of approximately 12. The Standard A.A.S.H.O. compaction was 96.6 percent.
