# Comparisons of Empty and Gross Weights of Commercial Vehicles 

LAURENCE L. LISTON, Transportation Economist, Office of Research and Development, and
STANLEY F. BIELAK, Transportation Economist, Office of Highway Planning, U.S. Bureau of Public Roads

#### Abstract

The need for a uniform weight classification base for commercial vehicles and the possibility of determining such a base from available information are described in this article. Because more adequate descriptions of commercial vehicles would permit better research and planning for the highways now being planned and built for the more than 100 million vehicles expected by 1972, an analysis has been made of available information.

Comparisons were made of data samples on commercial vehicles taken from the 1957 and 1961 loadometer studies and from special California vehicle records. Each sample group of data was satisfactorily representative of the total available information and correlations from selected groups of data were made by empty weights and by registered gross weights of vehicles.

The tabulations and the accompanying graphic materials are expected to be useful as guides in the solution of many vehicle classification problems. This analysis revealed that it would be very difficult, if not impossible, to develop a usable set of weight relationships from present registration data. However, the data considered in this study tend to give mutual support and the results of the 1957 loadometer study remain generally applicable.

- A SIGNIFICANT portion of highway research is dependent on the basic data that can be obtained on the numbers and types of motor vehicles that are, or are likely to be, in use. It is somewhat of an oddity that in this Nation of highly developed motor-vehicle mobility, one of the greatest single problems of highway research is the understanding, description, and cataloging of the numbers and kinds of vehicles in use for which highways must be provided.

There are nearly 80 million vehicles in the United States, and highways are now being planned and built for the more than 100 million expected 10 years from now. Yet, although each motor vehicle is required to be registered each year with a State motor vehicle department, it is possible to describe these 80 million vehicles in only the most general terms from the basic annual records. Although considerably more uniform information would be desirable on passenger vehicles the primary concern is the lack of uniform data on the types and weights of the truck fleet that at present is comprised of more than 12 million vehicles. The problems encountered are (a) the amount and quality of the data required and recorded on the annual registration application and on the registration certificate, and (b) the different weight bases used by the States for tax purposes. It often is not possible to combine, or to compare, the information on trucks registered in two neighboring States because the weight classification for tax purposes is entirely different. One State may register vehicles on the basis of the empty weight of the power unit, and another State may register its vehicles on the basis of the owner's declared maximum gross weight of vehicle and load. Data gathering is further complicated be-

[^0]

Figure 1. ilumber of trucks and combinations registered in 1931, 1951, and 1961, segregated by registration base; data for 1931 and 1951 are comparable but 1961 data include registrations in Alaska and Hawaii in the empty weight bar.
cause the State using empty weight has no means for gross weight identification, and the State using gross weight frequently does not require the empty weight of the power unit for its records. Any significant comparison of the effect of the bases used for truck registration should include the numbers of vehicles registered by each method. The application of the three main weight classifications employed in State registration systems to the truck fleets in 1931, 1951, and 1961 is shown in Figure 1. During the period from 1931 to 1961 truck registrations increased nearly fourfold, from 3.6 million to 12.3 million. (Data for the 1931 and 1951 comparisons were collected from 48 States and the District of Columbia; information from Alaska and Hawaii has been included in 1961 figures.)

Disparity in the methods of registration required has also been disappearing since 1931 when 26 States registered about 945,000 trucks on the basis of the manufacturers' rated capacities; 13 States registered approximately 1.6 million trucks on the basis of empty weight, and the remaining 10 States registered 1.1 million trucks on the basis of declared gross vehicle weight. By 1961 only Alabama retained the requirement for registration on the basis of manufacturers' rated capacity --239, 000 trucks were registered. The rest of the States required trucks to be registered either by empty weight or by some form of declared gross weight. A total of 3.3 million trucks were registered in 14 States by empty weight, and 8.8 million trucks were registered in 36 States by declared gross weight. Except for the small 2 -axle truck, commonly appearing as a pickup or panel vehicle and having characteristics similar to a passenger car, the many different types and sizes of trucks and combinations that compound the problems of classification and taxation are shown in silhouette in Figure 2.

Several samples of data that relate vehicle empty weights and declared gross weights have been compared to establish a set of usable weight correlations by visual vehicle

Figure 2. Commercial vehicle types as designated by code based orı axle arrangement.
classes. The resultant weight comparisons are given in tabular form and both the vehicle distributions and their percentage counterparts shown. These comparisons (Tables 11-17) provide an additional classification tool for research and planning activities.

The research covered by this report will have many uses, important to the Federal and the State governments. The data presented can be used as an aid in the analysis of the application and equitability of road-user taxes, and they are expected to enhance the effectiveness of administration of motor-vehicle tax laws. They will be useful in determining the probable effects of legislation proposed, and they also will be of value to those concerned with highway planning, and to industry in materials, product, and market research.

## VEHICLE CLASSIFICATION STUDIES

One of the early efforts to count and classify commercial motor vehicles was a comprehensive study of registrations and fees (1). Information for this study was compiled by the Bureau of Public Roads from State and local motor-vehicle records and from questionnaires that requested data on vehicles and taxes in considerable detail. Another study, known as the Nationwide Truck and Bus Inventory, was begun in 1940 by the Bureau of Public Roads in cooperation with the States. Although the work was eventually completed, it was expensive, and it used manufacturers' rated capacities as a uniform measure of truck weight. Since the use of that classification was rapidly waning, the study had limited value for comparing current vehicle classification data, and the results of the study have not been published.

The next major vehicle classification study was made by the Bureau of Public Roads, in cooperation with the States, to provide basic information for the highway cost allocation study that was required by Section 210 of the Highway Revenue Act of 1956. The findings of this classification study were included in the comprehensive series of highway cost allocation study reports made to the Congress, and also were published in 1960 by the Bureau of Public Roads as the "Classification of Motor Vehicles, 1956-57." This study is the most recent inventory of highway rolling stock, and it will be referred to herein as the classification study.

When the classification study was undertaken, an effort was made by Public Roads
and State authorities to obtain the needed data in each of the States. Intensive reviews were made of the existing registration records, special questions were added to some motor-vehicle registration application forms for the following year, and special questionnaires were mailed to vehicle owners by many States in an effort to obtain information to supplement the data in the registration files. A valuable lesson was learned during this study. The motor-vehicle data needed for highway research were unavailable from any public source in a usable form. Even if it had been possible to obtain a complete summary and analysis of the vehicle records of each State, the data obtained would have been so lacking in uniformity that it would have been impossible with the knowledge then available, to combine them into a workable, usable body of data for use in research. One result of these findings is the cooperative effort of the States and Public Roads to develop standard vehicle descriptions and information that will be useful to both government and industry. Substantial progress is being made under the auspices of the American Association of Motor Vehicle Administrators.

Many differences existed in the registration requirements and records of the States but the one that posed the greatest problem was the requirement of several States for registration of vehicles on the basis of empty weight or on variations of gross and empty weights. Most States registered and recorded vehicles on the basis of the owners' declared gross weight (the weight of the vehicle, fully equipped and ready for service, plus the maximum load to be carried).

When it is necessary, in studies of motor vehicies or motor-vehicle revenues, to bring the basic motor-vehicle data of all States into uniformity, a relationship must be established between the bases and all of the data must be converted to a uniform structure for analysis.

To analyze the composition of the vehicle fleet properly an understanding of the factors affecting the selection of the vehicles in use is necessary. Tax structures, terrain, kind of goods transported, and literally dozens of factors affect owners' vehicle selections. Some carriers may elect to buy lightweight power equipment to perform the same job that is done by another carrier with heavier and costlier power units. The lighter power units would depreciate more rapidly but, because of other factors, they might provide lower overall operation cost. The subject of vehicle ownership and operating costs is discussed in considerable detail in HRB Bull. 301 (2).

## SOURCES OF DATA FOR WEIGHT COMPARISONS

Traffic and Loadometer Data, 1957
During the course of the extensive 1957 motor-vehicle traffic counting, classification, and loadometer operations, approximately 600,000 vehicles were weighed, and data concerning empty weight, registered weight, make, body, axle arrangement, and other items on vehicle classification and operation were obtained. More than 150, $000 \mathrm{com}-$ mercial vehicles, for which weight data were complete, were selected from the group
 Gross vehicle weight was available from the registration certificates for only vehicles registered on that basis, but it is believed that a good representative sample was obtained because States using this basis were very well distributed geographically. The data concerning the 150,000 commercial vehicles are referred to herein as the "1957 loadometer data." Information from more recent weighing studies and spot vehicle classification counts made by the States have been added to the 1957 loadometer data. The locations of the weighing stations were selected with the objective of making the data collected from them representative of the vehicles being used in that area.

## Loadometer Data, 1961

Rather than wait until the 1961 loadometer study had been completed and the complete record of weighings was available for use, a special group of data was collected from a limited sample of vehicles throughout the United States. This sample was obtained as a part of the regular loadometer study, but was collected at the first station or first tow stations operated in each State at the beginning of the weighing operations. The study instructions stipulated that vehicles were to be weighed at each station until at
least 10 loaded and 10 empty vehicles of each visual type (Fig. 2) had been observed.
A field crew member was assigned to interview each driver and to obtain registration card information while the vehicle was being weighed by other members of the crew. These data were placed on punched cards, which were forwarded to the Washington of fice of the Bureau of Public Roads. In order to check the accuracy of the sample, Public Roads sent the record of each of these vehicles to the State in which it was registered to be verified against the registration file. It is believed that this check eliminated many of the inconsistencies, which might otherwise have gone undetected, and that data for the resultant group of vehicles identified herein as the "1961 loadometer data" have a relatively high degree of accuracy. Although the sample was not expanded, a comparison of the data with those obtained from other sources showed the information to be representative in all major weight cells. The usable sample from the 1961 loadometer data totaled approximately 14,000 vehicles, and the information gathered included empty and gross weights, vehicle type, number of axles, body type, class of use, some information on fuel used, year model, make of vehicle, and commodity carried. Only the information that applies specifically to weight comparisons has been summarized here. Processing of the remaining data is in progress and, if these data are found to be representative, they will be used in other studies.

Some unexplained differences were noted in a comparison of the 1957 and 1961 loadometer data. These differences probably were caused by the highway system coverage and the distribution of the loadometer stations. Because of the scope and purpose of the 1957 loadometer study, more urban stations were included and a greater coverage of secondary and local road systems was obtained. The 1961 loadometer data, however, are more indicative of the type of vehicles used on main rural highways.

## California Data

The third group of data was obtained from the State of California for vehicles registered under the Uniform Proration Compact. California maintains an excellent file on motor-vehicle fleets that are registered in other States on different registration bases and that are operated in California under the Proration Compact. Uniform empty and gross weight data and other vehicle information were available for these vehicles. The California authorities permitted the authors to use the information and provided much assistance in interpreting it. This availability of another source of data was an important factor in the decision to present this study.

Unlike the truck samples obtained in the loadometer surveys, the California data represented principally over-the-road fleets from the Western States. The records included the declared gross vehicle weight of the vehicle or combination; the empty weight of the power unit; and the type of carrier, make, year model, and number of axles; and the type of motor fuel used. Data on approximately 8,000 vehicles were supplied by the State, and information on 6,700 has been used in the present comparisons. Information on approximately 1,300 vehicles could not be included in the study because one or more of the basic weight factors had not been included in the reports to the State.

## Data from Other Sources

The State motor-vehicle registration authorities make their annual registration counts, by vehicle type, available to the Bureau of Public Roads and other interested groups. These data are consolidated (3) for use by government transportation and planning authorities, industry marketing groups, and private individuals. A few States prepare special tabulations on commercial vehicles by weight classes for their own uses, and copies of these have been supplied to the Bureau for studies of vehicle characteristics, distribution, and use.

## DISCUSSION OF DATA

## Registered Gross Weights by Vehicle Types

Table 1 summarizes the vehicles registered on a gross weight basis for which empty weights were available; these data were obtained in the 1957 and 1961 loadometer surveys.

Table 1.-Trucks and combinations, observed during 1957 and 1961 loadometer studies, grouped by number of axtes and by registered gross vehicle weights ${ }^{1}$

1 Data from 1957 and 1961 special, field - weighing reports are combined in this table. The portion of the tahle boxed ly heavy lines represents 90 pereent or more of the vehieles in each whicle type.

Numbers and percentages of vehicles of each type are given by registered gross weights. Heavy lines in the table enclose data for approximately 90 percent of the vehicles in each visual type. The extremes, representing approximately 10 percent of the vehicles, are "fenced out" above and below the main group. Thus a visual comparison can be made of the total range of the data. This comparison shows the approximately 90 percent spread of gross weights for each of the vehicle types, and it illustrates that as the vehicles became larger the gross weight range was smaller. Registered gross weights for each vehicle type, however, overlap the weights for both adjacent vehicle types.

The 1961 loadometer data presented in this study for the 2 -axle trucks cannot be separated into 4 -tire and 6 -tire classes. Other sources (4) have shown however that, taken as separate groups, the 2 -axle, 4 -tire class would show a rapid diminution of numbers over $8,000 \mathrm{lb}$ and, with the greater load flexibility permitted by additional tires, the 2 -axle, 6 -tire class would peak at about 12,000 to $18,000 \mathrm{lb}$ and would taper off slowly in numbers at approximately $28,000 \mathrm{lb}$. Within the enclosed area of the table, the data for successive vehicle types form a group of steps to the larger gross weights.

## Comparison of 1957 and 1961 Loadometer Data and California Data

Table 2 shows the California data by registered gross weights and by visual vehicle types. The heavy lines enclose approximately 90 percent of the vehicles in each type. A comparison of the vehicle distributions from the loadometer weighings in Table 1 with those obtained from the California data reveals considerable disparity in the information from the two sources. Because vehicles represented in the California data were used principally in intercity service, much less dispersion in gross weights was noted in these data than in the information obtained from the loadometer studies.

Frequency distributions and least squares comparisons of empty to gross weights are shown in Figures 3 through 9 for the main visual types of vehicles. The California data, represented by the medium-length dash least squares lines in the upper panels of these figures, with certain exceptions, showed that the average empty weights of vehicles in relation to given gross weights were higher than the empty weight to gross weight relations recorded by loadometer data. A similar empty weight relationship was not recorded for the 3-S2 vehicle combinations; the slope of the line for the 1961 loadometer data (Fig. 7) suggests the effect of too small a sample. However, this relationship of the empty to gross weight probably is not entirely accurate as the Public Roads' vehicle classification counts indicate that use of the $3-S 2$ vehicle combinations has become more widespread geographically than in 1957, and therefore the relationship of empty to gross weight could have been different than shown by the 1961 loadometer data.

As shown in Figure 8, an exception to the higher empty weights in relation to gross weights was recorded in the 1957 loadometer data, which included information on an unusually large number of 3-2 truck-trailer combinations registered at 50, 000 to $55,000-\mathrm{lb}$ gross combination weight and reported as having empty weights of more than $16,000 \mathrm{lb}$ for the truck alone. Such a reported distribution of so many 3-2 combinations at 55,000 pounds in 1957 was not normal because in the classification study nearly 97 percent of the 3-2 combinations were reported to have been registered at more than $60,000-\mathrm{lb}$ gross combination weight.

A percentage comparison of the gross weight distribution of combined 1957 and 1961 Ioadometer data and of the California data with the nationwide gross weight distribution of all vehicles of each type reported in the 1956-57 classification study is given in the bottom panels of Figures 3 through 6. The loadometer data distribution by gross weight was close to that for the classification study (Fig. 3). This close relationship implies that the gross weights for vehicles sampled in the loadometer studies were relatively proportional to the gross weights for all such vehicles registered. But, as stated earlier, the California data consisting largely of registrations of over-the-road 2 -axle, 6 -tire vehicles showed a much larger sample for vehicles having 18, 000- to $26,000-\mathrm{lb}$ gross weights. The 2 -axle classification given in Figure 3 includes both the 2 -axle, 4 -tire and the 2 -axle, 6 -tire vehicles. Nationwide more than 90 percent of the 2 -axle, 4 -tire vehicles were registered for gross weights under 8, 000 lb . More than 67 percent of the 2 -axle, 6 -tire trucks were registered for gross weights in excess

of $12,000 \mathrm{lb}$, and nearly 47 percent was registered for gross weights in excess of $16,000 \mathrm{lb}$.

Figures 4 through 9 show that the gross weights of the sampled vehicles in the loadometer studies follow closely the gross weight distributions of the vehicle population. Gross weight comparisons for information from the classification study have not been included in Figures 7 through 9 for the $3-\mathrm{S} 2,3-2$, and the $2-\mathrm{S} 1-2$ vehicle combinations because these vehicles generally are registered for the State maximum permitted gross weights of over $60,000 \mathrm{lb}$ and their registrations were shown in the classification study in that maximum weight class.

## Combined Loadometer Data

In Figure 10, straight lines illustrate the empty to gross weight relationships obtained by the least squares method. The lines were based on the combined data from the loadometer surveys, and they provide a quick visual comparison of relationships for five vehicle types. The lines for the single-unit trucks follow a parallel course, they overlap in the gross weights from 22,000 to $32,000 \mathrm{lb}$, and they are separated by about $1,500 \mathrm{lb}$ of empty weight. This greater empty weight is accounted for largely by the third axle in the 3 -axle truck. The slope of these two lines is much steeper than the slope of the lines for the tractor power units, shown in combination as $2-\mathrm{S}-1,2-\mathrm{S} 2$, and $3-52$, because the payload carrying body is included in the empty weight for singleunit trucks but is not included for the combination vehicles. A considerable gross vehicle weight overlap is shown for the $2-$ S1 and $2-$ S2 combinations because of differences in size and weight requirements; some States require an additional axle to carry loads that can be carried by the $2-$ S1 combination in other States. Also, factors of terrain, power requirements, and types of loads carried are considered by operators in their choice of vehicles.

Comparison of 1957 and 1961 Loadometer Data

A percentage comparison of the distribution of gross weights of vehicles from the 1957 loadometer data with the distribution of the gross weights of vehicles from the 1961 loadometer data is given in Table 3. The 1957 study was designed to sample vehicles on all types of rural and urban

1 The jortion of the table boxed by heavy lines tepresents 90 percent or more of the vehteles in eate vehtele 1 ype

Figure 10. Relationship of the recorded empty weights of the power units to the registered gross weights of the vehicles based on combined 1957 and 1961 loadometer data.
highways as uniformly as possible, but the 1961 data were obtained to a larger extent at stations on main rural roads. The comparison indicates that the traffic on main rural roads has a much greater concentration of heavy vehicles than the total traffic on all types of rural and urban highways.

Table 4 gives a distribution of the same vehicles by empty weights of the trucks and power units for the 1957 and 1961 loadometer surveys. The information in both tables shows that the empty and gross weights were consistently heavier in the 1961 loadometer data. The percentage distributions for each weight group, within each vehicle type, have been cumulated inversely as an additional check on the differences between the 1957 and 1961 loadometer data. At first glance it might appear that trucks and combinations have gotten heavier since 1957, and to some degree this may be true. However, evidence from continuing vehicle and classification counts has led the authors to conclude that most of the difference between the two sets of data was caused by the difference in the size and scope of the samples.

To show a more complete cross-section of information on the three vehicle types given in Tables 3 and 4, a set of two-way frequency distributions of empty weight to gross vehicle weight has been given for each of the three vehicle types separately for the 1957 and 1961 loadometer samples in Tables 5 through 10. With the data arrayed in this manner it is possible to examine either the frequency distribution by empty weights of vehicles in a given class interval of registered gross weight, or the distribution by registered gross weights of vehicles in a given class interval of empty weight. Both numerical and percentage distributions are given, and heavy lines enclose approxi-
'able 3.-Comparison of relative numbers of motor vehicles observed in the 1957 and 1961 loadometer studies by gross vehicle weight groups

1 Percentages in this column are on inverse cumulation of the pereentages in the preceding columin

those having light empty weights and heavy gross weights constituted only a small proportion of all vehicles in that class. A large proportion of some vehicles of a given empty weight were concentrated in two or three gross-weight intervals.

## Conversion Tables

Tables 11 through 17 give the comparisons of empty weights to gross weights of the combined 1957 and 1961 loadometer data for seven of the most commonly used types of vehicles. Information on all the vehicles for which the weight data collected was usable for this article has been included. The numbers and percentages (horizontally) of the gross weight distribution of these vehicles are given. The numbers of vehicles that had unusual empty to gross weight relationships have been included even though they represent a very small percentage. The 166,000 vehicles that are classified by weights are representative of the national distribution of vehicles and their classification provides a tool for the solution of problems of weight conversions. These data will be useful for making revenue estimates, as well as being a working tool in many areas of market research.

The process of conversion is illustrated as follows. Assume that Table 13 was considered appropriate, in a given situation, for converting 3 -axle, tractor-semitrailer (2-S1) combinations registered by empty tractor weights into an array representing their probable distribution by registered gross weight of combination in a State requiring that method of registration. The number of vehicles in each class interval of empty weight should be multiplied by the corresponding horizontal percentages in Table 13, and the numbers so obtained should be added vertically to obtain the distribution by registered gross weights. Conversely, a conversion from registered gross weight of combination to empty weight of tractor can be performed by distributing the number of vehicles in each gross weight class interval proportionate to the corresponding vertical distribution of vehicles by empty weights in Table 13 and then adding the numbers so obtained horizontally.

Figure 1l. Scattergram of average empty weight of tractor trucks and of semitrailers by registered gross combination weight, and lines of best fit (California data).

## Weight Relationship of Trailer and Combination

In Figure 11, a scattergram of the mean average empty weights and the lines of best

Table 18.-Empty weight to gross weight ratios of single-unit trucks and tractorsemitrailers, at selected gross vehicle weights

| Vehicle type | Ratio of gross vehtcle weight to- |  |
| :---: | :---: | :---: |
|  | Empty weight of power unit only | Empty weight of entire vehicle |
| Single-unit trucks: |  |  |
| 2-axi, 000 pounds GVW |  |  |
| 32,000 pounds GVW | 2.7 |  |
| 3 -axle |  |  |
| 22,000 pounds GVW | 2.2 |  |
| 50,000 pounds GVW | 2.8 |  |
| Vehicle combinations: |  |  |
| 3-axle (2-81) |  |  |
| 20,000 pounds GVW | 3.2 | 1.3 |
| 50,000 pounds GVW. | 5.5 | 2.5 |
| 4-axle (2-S2) |  |  |
| 30,000 pounds GVW | 3.9 5.8 | $\begin{aligned} & 1.7 \\ & 2.8 \end{aligned}$ |
| 65,000 pounds GVW. | $5.8$ | 2.8 |
| 5 -axle (3-S2) |  |  |
| 50,000 pounds GVW. | 4.0 | 2.1 |
| 75,000 pounds GVW | 4.8 | 2.7 |

fit reflects the approximate empty to gross weight relationship of tractors and semitrailers shown in the California data. Straight lines were computed for 1- and 2-axle, semitrailers and for the 2- and 3-axle tractor trucks used with them. The scattergram shows a wide range of empty weights of semitrailers in each type of tractor-semitrailer combination and at all gross weight levels. However, regardless of the type of combination, whether $2-S 1,2-S 2$, or $3-S 2$, even with substantial increases in gross combination weights, only moderate increases were noted in the semitrailer average empty weight. But for the tractor truck power units a much steeper gradation in empty weight in relation to gross weight is shown.

## Empty Weight to Gross Weight Ratios

Employing the power unit relationship used in Figure 10 and the data from the semitrailer line in Figure 11, empty weight to gross weight ratios given in Table 18 indicate

Figure 12. Range of recorded empty weights of 2-axle trucks registered by gross vehicle weights, based on the combined 1957 and 1961 loadometer data.

Figure 14. Range of recorded tractor empty weights of 3-axle, tractor-semitrailer combinations (2-S1) registered by gross vehicle weights, based on the combined 1957 and 1961 loadometer data.

Figure 13. Range of recorded empty weights of 3-axle trucks registered by gross vehicle weights, based on the combined 1957 and 1961 loadometer data.

Figure 15. Range of recorded tractor empty weights of 4 -axle, tractor-semitrailer combinations (2-S2) registered by gross vehicle weights, based on the combined 1957 and 1961 loadometer data.

Figure 16. Range of recorded tractor empty weights of 5-axle, tractor-semitrailer combinations (3-S2) registered by gross vehicle weights, based on the combined 1957 and 1961 loadometer data.

Figure 18. Range of recorded tractor empty weights of 5 -axle, tractor-semitrailer full trailer combinations (2-SI-2) registered by gross vehicle weights, based on the combined 1957 and 1961 loadometer data.
relationships that would permit a point, or be used for any purpose.

Figure 17. Ronge of recorded track empty weights of 5 -axle, truck full-trailer combinations $(3-2)$ registered by gross vehicle weights, based on the combined 1957 and 1961 loadometer data.
that vehicle gross weights ranged from 1.2 times the empty weight at the low-weight interval of the smallest vehicle to a high of 2.8 at the high-weight interval for the larger vehicles. It may be of significance that a vehicle type selected and registered at near the maximum weight of its class is capable of operating with the most favorable empty weight to gross weight ratio. The results for the upper gross weight limit of each vehicle type are similar for all five vehicle types.

## Range of Conversion

Figures 12 through 18 show both the wide range of empty weights for each gross weight, and the range that contained approximately 90 percent of the vehicles. Although the $\mathcal{y} u$ percent range eliminates the extremes, the band of weight comparison is still too wide to allow the use of a point of conversion. It would be very difficult, if not impossible, to develop a usable set of weight
even a narrow band, of weight conversion to

## CONCLUSIONS

In general, data from the vehicle weight comparison series included in "Classification of Motor Vehicles, 1956-57, " the information from the 1957 and 1961 loadometer data, and the California data tend to give strong mutual support. Therefore, the results of the 1957 loadometer study remain generally applicable, and this study is a further refinement of the data. In applying weight comparison factors from any of the data, however, some caution should be exercised to allow for the increasing trend toward use of diesel-powered vehicles and for the anticipated effects of any changes in vehicle size and weight laws.

The 1961 loadometer data and the California data have provided information that permits the addition of another large vehicle combination to the vehicle weight comparison series-the 2-S1-2. This combination was not covered in earlier studies. Additional investigation in this area is warranted, not only to obtain more data on the vehicle weight relationships, but also to keep the findings from these investigations up-to-date. Comprehensive studies of vehicles on a carefully tailored regional basis would provide information even more usable. In the selection of regions for these studies, the State size and weight restrictions, the geographic features, and the predominance of certain types of vehicles favored for their adaptability to commerce or terrain of the region should be considered.

Tables 11 through 17 give a reasonable nationwide picture of the relationship between recorded empty and declared gross weights of different vehicle types. These comparisons demonstrate clearly that it would not be practicable to try to develop a set of weight relationships that would permit a point, or even a narrow band, of weight conversion to be used for any purpose. Conditions in individual States may be such that modifications or adaptations of the data may be required before they can be applied. However, the data provide a useful tool that can serve as a guide, or reference point, for local conversion problems. The local situation would have to dictate any adjustment factors necessary to make the data in these tables applicable to the problems being considered.
