the one- and the two-dimensional analyses gave the same magnitude for the residual stress problem, but occurrence in the cross section differed. With the presence of unsymmetrical thermal boundary conditions, therefore, a one-dimensional approach (Figure 11) could be misleading with respect to a residual stress distribution.

Therefore, because of the multitude of possible thermal surface conditions, a simple analytical model is not feasible at this time. However, most design specifications account for the possible combinations of loading extremes by allowing a percentage increase (usually 33 1/3 percent) above the specified working stress limitation. Therefore, it should prove adequate to specify a 600 psi increase in the actual working stress, considering the percentage increase in the allowable working stress. Until more extensive work is performed, such a simplified approach seems prudent.

Seasonal and Diurnal Behavior of Concrete Box-Girder Bridges

K. NAM SHIU

ABSTRACT

Measurements from three instrumented bridges in different parts of the United States were used to assess seasonal and diurnal behavior of concrete box-girder bridges. Effective bridge temperatures were used to evaluate seasonal thermal changes in bridges. Effective bridge temperature is defined as the temperature that governs longitudinal bridge movements. The effective bridge temperatures followed the same seasonal fluctuation as monthly average air temperature at the bridge site. Measured temperature differentials from top to bottom slabs for the three box-girder bridges were between +20°F and -10°F (+11.1°C and -5.6°C) regardless of geographic location. Temperature differentials were calculated by subtracting temperatures of the bottom slab from those of the top slab. Diurnal behavior of one bridge was continuously monitored for 24 hours during each of the four seasons. Longitudinal strains and temperatures were used to evaluate effects of nonlinear temperature gradient on bridge behavior. Internal thermal stresses at the instrumented bridge sections are reported.

Most materials expand with a rise in temperature and contract with a fall in temperature. In the past designers have assumed that structures respond lin-
early to temperature changes. Recent measurements on box-girder bridges (1-5) indicate that thermal response of structures is highly nonlinear and complex. Therefore, design provisions for thermal effects based on assumed linear behavior may be misleading.

Overseas researchers have conducted extensive investigations on thermal behavior of bridges (1,3-5). As a result, thermal provisions based on nonlinear behavior have been incorporated into design codes in Great Britain and New Zealand. However, no similar provisions exist in the AASHTO specifications (6).

Although no major structural distress has been attributed to temperature alone, temperature effects have contributed to structural distress reported in recent years (2,5). As more and more bridges are built with longer spans and complex sections, thermal response of bridges becomes an increasingly important factor to consider in design.

THERMAL BEHAVIOR OF CONCRETE BRIDGES

The thermal response of bridges is discussed in terms of two deformation categories: (a) overall longitudinal movements and (b) temperature-induced curvatures.

Overall Longitudinal Movements

Bridges respond primarily in the longitudinal direction to gradual seasonal temperature variations. Overall longitudinal expansion of a simply supported beam is shown in Figures 1a and 1b. With a gradual temperature rise, the beam expands uniformly in the longitudinal direction by \( \Delta L \). The temperature distribution causing this thermal movement is a uniform temperature distribution, \( \Delta T \), across the bridge section, as shown in Figure 1b.

If longitudinal movement of the beam is fully restrained, internal stresses will be induced in the beam and no thermal strains will occur. If partial longitudinal restraint is provided, a combination of thermal strains and thermal stresses will occur.

Temperature-Induced Curvature

In addition to seasonal temperature variations, bridges experience daily temperature variations. As the sun shines on a bridge, the deck heats up. The deck generally responds much faster than the rest of the bridge section. Consequently, temperature gradients exist between the top and the bottom of the bridge superstructure. In the case of a simply supported beam, the beam cambers as shown in Figure 1c. It is generally assumed that the temperature distribution effecting such thermal movement is a linear gradient across the beam section.

However, actual temperature distributions across bridge sections are nonlinear (1-5). Investigations (1,3) have shown that temperature distribution can be more realistically represented by a fifth-order parabola.

For a given nonlinear temperature gradient, the bridge deforms to attain an effective curvature. Because plane sections are assumed to remain plane according to beam theory, the resulting strain has to vary linearly across the bridge section. However, concrete tends to expand or contract according to the coefficient of thermal expansion; consequently, internal restraint stresses are induced, as shown in Figure 1d. Restraint stresses occur in all sections with nonlinear temperature distributions. Some researchers (2,3) have indicated that restraint stresses can be substantial.

FIELD MEASUREMENTS

To understand the actual thermal behavior of bridges, three long-span box-girder bridges were instrumented during construction by the Construction Technology Laboratories. They are Kishwaukee River Bridge (7) in Illinois, Denny Creek Bridge (8) in Washington, and Linn Cove Viaduct (9) in North Carolina. A summary of the characteristics of the three bridges is given in Table 1.

Kishwaukee River Bridge, shown in Figure 2, was instrumented to investigate time-dependent behavior of segmental box-girder bridges. Three sections of a selected span were instrumented. The sections were located next to the pier, at quarter span, and near midspan. Measurements included longitudinal restraint stresses, air and concrete temperatures, and deflections. Locations of temperature and strain measurements at a section are shown in Figure 3. Detailed description of the instrumentation program is given elsewhere (7). Readings were taken seasonally for a period of 5 years. In addition, four sets of 24-hour continuous readings on the bridge were taken to monitor diurnal bridge behavior in different seasons.

Denny Creek Bridge, shown in Figure 4, was instrumented to determine time-dependent behavior of a cast-in-place, stage-constructed, box-girder bridge. The instrumentation layout was similar to that used in the Kishwaukee River Bridge. Bridge sections located next to the pier, at quarter span, and near midspan were instrumented. Details of the instrumented span are reported elsewhere (8). Locations of the temperature and strain measurements on each section are shown in Figure 5. Readings were taken periodically during 2 years.

Linn Cove Viaduct in North Carolina is a continuous, precast, box-girder bridge with a highly unusual geometric configuration as shown in Figure 6. The objective of instrumentation was to measure...

and evaluate temperature differentials, thermal and torsional strains, and prestress losses (9). The instrumentation scheme was similar to that used at the Kishwaukee River Bridge. Bridge sections next to the pier, at quarter span, and near midspan of one span were instrumented. Locations of the temperature and strain measurements on each section are shown in Figure 7. A detailed description of the instrumentation program on Linn Cove Viaduct is given elsewhere (9). Readings were collected for approximately 500 days during and after construction.

SEASONAL BEHAVIOR

Effective bridge temperature was used to evaluate seasonal behavior for each instrumented bridge. Effective bridge temperature is defined as the temperature that governs the longitudinal movements of the superstructure. A method of calculating effective bridge temperatures is described elsewhere (4). In this paper, averages of temperatures measured in the top slab, in the web, and in the bottom slab of the box girder were used to calculate the effective bridge temperatures.
Temperature Measurements

Temperature and Strain Measurements

FIGURE 6 Linn Cove Viaduct.

A comparison of the calculated effective bridge temperatures of the Kishwaukee River Bridge and the monthly average air temperature near the bridge site (10) is shown in Figure 8. Monthly average air temperatures are based on temperature records since 1945. The effective bridge temperature follows the monthly average air temperature fluctuation. Overall longitudinal movements of the Kishwaukee River Bridge are proportional to variations in monthly average air temperature near the bridge site.

A similar observation was made for the Denny Creek Bridge in Washington as shown in Figure 9. No comparison was performed for the Linn Cove Viaduct.

because the collected data were very limited. At Linn Cove readings were taken over a period of 1 year with collected data points clustered in two seasons only. Consequently, comparison of effective bridge temperatures with monthly air temperatures can be misleading.

On the basis of these comparisons, it is concluded that longitudinal thermal movements of concrete box-girder bridges can be estimated by using the average air temperature at the bridge site.

The ranges of temperature specified in the AASHTO specifications (6) for designing concrete structures are a temperature rise of 10°F (17°C) and a temperature fall of 40°F (22°C) in moderate climates, and a temperature rise of 35°F (19°C) and a temperature fall of 45°F (25°C) in cold climates. However, if the average monthly air temperature (10) at Kishwaukee River Bridge would have to accommodate a temperature rise of 32°F (18°C) and a temperature fall of 32°F (18°C) relative to the annual mean temperature at the bridge site. For the Denny Creek Bridge, the temperature range would only be a temperature rise of 24°F (13°C) and a temperature fall of 18°F (10°C). It is therefore suggested that monthly average air temperature at bridge sites may be used as a guide for determining the overall longitudinal behavior of bridges as an alternative to the ranges given in the AASHTO specifications (6).

Variation of measured differentials between the temperature of the top and of the bottom slabs of the three instrumented bridges with time is plotted in Figure 10. Temperature differentials were calculated by subtracting temperatures of the bottom slab from those of the top slab. As shown in Figure 10, temperature differentials for the three bridges were within the range of +30°F and -10°F (+11°C and -6°C) regardless of their geographic location. This implies that concrete temperature differentials in box girders are independent of air temperature variations due to change in geographic location. However, it is noted that the observation was based on a limited data sample. More data are needed to confirm this observation. Further investigations on temperature differentials of box girders are recommended.

DIURNAL BEHAVIOR

Four sets of 24-hour measurements were made on Kishwaukee River Bridge. Measurements included air temperature inside and outside the box girder, concrete temperature, and longitudinal concrete strains. Daily variations in the measured air temperatures for four seasons are shown in Figure 11. Air temperature outside the box girder fluctuated more than air temperature inside.

Temperature distributions in the top and in the bottom slabs of the segment next to the pier in the summer and winter of 1979 are plotted in Figure 12. Values shown at the bottom of the slab are the ambient air temperature. Because of the delayed response of concrete to outside air temperature, temperature distributions across the box section were nonlinear.

Longitudinal strains and temperatures measured during the 24-hour periods were used to evaluate effects of diurnal temperature changes on bridge behavior. Two procedures were used to adjust measured strains for thermal expansion or contraction of both concrete and strain gauges to a standard temperature of 73°F (23°C).

In the first procedure, concrete and strain gauges were assumed to expand or contract proportionally to their respective coefficient of thermal expansion. This simple procedure assumes unrestrained movement of concrete and strain gauges.

In the second procedure, effects of nonlinear temperature gradient were included. The following steps were used to adjust strain readings to the standard temperature of 73°F (23°C):
1. Measured temperature data were fitted to a fifth-order parabola to determine temperature distribution across the box girder;
2. Curvature of the section resulting from the calculated parabolic temperature distribution was calculated;
3. From the computed curvature, an equivalent linear temperature distribution to cause the same curvature was determined;
4. Using the equivalent temperature distribution, effective temperatures at the location of the strain gauges were calculated; and
5. Because effective temperatures corresponded to thermal movements across the section, strain readings were adjusted from the calculated effective temperatures to 73°F (23°C).

Comparisons of strains calculated according to the two temperature correction procedures are shown in Figures 13 and 14. Dotted lines in the figures represent reduced strain data using the first temperature correction procedure. Solid lines represent reduced strain data using the second temperature correction procedure. Figure 13 shows daily variation of strains measured in the top slab and Figure 14 represents daily variation of strains measured in the web of the box girder. The difference between strains obtained from the two temperature correction procedures is the restraint thermal strain corresponding to the induced thermal stress. When the modified compressive strains at each location were less than the strains calculated with the assumption of free expansion and contraction, tension restraint stresses were induced. Likewise, when the modified compressive strains were larger than the strains calculated using the free thermal movement assumption, compressive stresses were induced in the section.

In Figures 13 and 14, maximum restraint strains ranged from 20 millionths in compression to 20 millionths in tension. Measured concrete modulus of elasticity was between 4,190 ksi (28.9 GPa) and 4,760 ksi (32.8 GPa). For simplicity, a modulus of 5,000 ksi (34.5 GPa) was used to calculate the equivalent restraint stresses. Calculated restraint stresses ranged from 100 psi (689 kPa) in tension to 100 psi (689 kPa) in compression. The restraint stress range is based on a limited number of field measurements. Therefore, reported stress range should not be treated as the range of maximum anticipated restraint stress levels.

The calculated restraint stresses of 100 psi (689 kPa) are used to calculate the equivalent restraint stresses.
kPa) in magnitude is substantially less than stresses predicted from the modified New Zealand temperature distribution. Restraint stresses calculated for the Pennsylvania box-girder bridge (2) using the modified New Zealand temperature distribution (1, 3) were reported to range from 488 psi (3362 kPa) in tension to 577 psi (3976 kPa) in compression. In addition, restraint stresses were quite transient. Internal restraint stresses increase and decrease within hours. Although restraint stresses are present only for a short time, some consideration should be given to these stresses in design.

CONCLUSIONS

On the basis of the preceding discussion, the following conclusions are drawn:

1. Annual variation in the effective bridge temperature was found to be quite similar to the variation in monthly average air temperature at the bridge site.

2. Measured temperature differentials between the top and the bottom slabs of three box-girder bridges ranged between +20°F and -10°F (+11°C and -6°C). Measured temperature differentials seem to be independent of geographic location. Further investigations of temperature differentials in box girders are needed.

3. For the Kishwaukee River Bridge, internal restraint stresses from nonlinear temperature distribution varied between 100 psi (689 kPa) in tension to 100 psi (689 kPa) in compression. The calculated restraint stresses were substantially less than stresses computed using the temperature provision of the New Zealand Code (2).

4. Internal restraint stresses were transient in nature.

ACKNOWLEDGMENT

Data used in this paper were obtained from three investigations conducted by the Structural Experimental Section of the Construction Technology Laboratories, a division of Portland Cement Association, under the direction of D.M. Schultz, Manager, H.G. Russell, Director, and W.G. Corley, Divisional Director. Sponsors of the investigations were the Illinois Department of Transportation, the Washington State Department of Transportation, and the FHWA.
