# Effect of the $65-\mathrm{mph}$ Speed Limit on Speeds in Three States 

Mark Freedman and Joy R. Esterlitz

#### Abstract

Following the April 1987 enactment of federal law permitting 65mph speed limits on rural Interstate highways, 40 states adopted higher speed limits by the middle of 1988. Nondetectable radar was used to measure speeds in three states to evaluate the effect of the $65-\mathrm{mph}$ speed limit on speeds of free-flowing vehicles on Interstate highways during daytime off-peak periods (9:00 a.m. to 4:00 p.m.). In New Mexico, rural and urban speeds were measured at 2 -month intervals over a 2 -year period after the speed limit was increased in April 1987. In Virginia and Maryland, rural speed data were collected immediately before and after Virginia implemented the $65-\mathrm{mph}$ limit in July 1988 and data collection was repeated at 3 -month intervals for 1 year. Two weeks after the $65-\mathrm{mph}$ speed limit began in Virginia, mean and 85 th-percentile speeds of cars were higher by almost 3 mph , whereas the speed of tractor-trailers (still limited to 55 mph ) was unchanged. The proportion of cars exceeding 70 mph nearly doubled. Speeds of cars and trucks in neighboring Maryland (with $55-\mathrm{mph}$ speed limit) did not increase during the same 2 weeks. A longer-term trend of increasing speed was also found in Virginia. In contrast, car speeds in Maryland showed no upward trend, but tractortrailer speeds have increased to the same level as in Virginia. In New Mexico, average speeds of passenger cars and light trucks on rural highways increased nearly 3 mph within 9 months of the $65-\mathrm{mph}$ law and have since continued to increase. The proportion exceeding 70 mph grew nearly fivefold for cars and doubled for heavy trucks. Urban highway speeds in New Mexico have shown a slight net increase over 27 months, while also exhibiting pronounced seasonal variation.

When the $55-\mathrm{mph}$ national speed limit was established in 1974 as part of a broad effort to reduce energy consumption in the United States, average speeds on rural Interstate highways (as determined by each state and reported by the FHWA) dropped from 65.0 mph in 1973 to 57.6 mph (1). Since 1974, speeds both on urban and rural Interstate highways have gradually increased. Although the procedures used by states to measure, analyze, and report speeds changed between 1980 and 1982, by 1986 the average speed on rural Interstate highways increased to 59.7 mph and the 85 th-percentile speed (the speed at or below which 85 percent of the vehicles are traveling) was $66.2 \mathrm{mph}(1)$. By 1986, 76 percent of drivers exceeded 55 mph and 18 percent exceeded 65 mph on rural Interstate highways. As many as 90 percent of vehicles were traveling faster than 55 mph and more than 30 percent surpassed 65 mph in some states (1).

In April 1987, Congress enacted the Surface Transportation and Uniform Relocation Act permitting states to set a maximum $65-\mathrm{mph}$ speed limit on certain highways in the Interstate system located outside urbanized areas with populations of

[^0]50,000 or more. Further, in December 1987, Congress established a demonstration program that allowed up to 20 states to adopt a $65-\mathrm{mph}$ speed limit on three additional classes of highways outside of urbanized areas. By late 1988, 40 states had raised speed limits to above 55 mph on almost $29,800 \mathrm{mi}$ of Interstate highways and 16 states had done so on approximately $2,200 \mathrm{mi}$ of non-Interstate highways (personal communication). Nearly all of these highways are posted at 65 mph for cars, whereas 15 states restrict certain vehicles (buses, trucks, and others) to lower speeds.

As speed increases, vehicles become more difficult to control, drivers have less time to react to other vehicles and roadway hazards, stopping distances are greater, and more energy is imparted in collisions thus increasing their severity. Research has shown that rates for injury and property damage in crashes increase exponentially with precrash speed and the percentage of drivers and front-seat passengers injured increases monotonically with speed at impact $(2,3)$. Speed limits are intended to improve safety by preventing excessive speed. Reduced and more uniform travel speeds resulted in an estimated 3,000 to 5,000 fewer deaths in the year following implementation of the $55-\mathrm{mph}$ national speed limit. In addition, an estimated 4,000 fatalities were prevented in 1983 by the lower speeds, even though average speeds had increased somewhat above the 1974 level (4).

Two time series studies are presented of speeds on rural (and some urban) Interstate highways in three states: Virginia and New Mexico, which changed to a $65-\mathrm{mph}$ speed limit (although heavy trucks are still limited to 55 mph in Virginia), and Maryland, which retained the $55-\mathrm{mph}$ speed limit. The objective of the speed studies was to determine the short- and longer-term effects of the $65-\mathrm{mph}$ speed limit change on mean speed, speed distribution, and compliance for cars, light trucks, and tractor-trailers on rural Interstate highways. Virginia and Maryland data were also used to evaluate the immediate effect of the increased speed limit, and New Mexico data were used to examine urban Interstate highway speeds.

## METHODS

The New Mexico study began in April 1987 two weeks after the speed limit was raised. Speeds were measured at about 2-month intervals for 27 months until June 1989. The Virginia study was performed 2 weeks before the speed limit increase to 65 mph (July 1, 1988) and 2 weeks after the new speed limit was posted with follow-up data collection every 3 months for 1 year until July 1989. Data were collected simultaneously in adjacent Maryland, which retained the $55-\mathrm{mph}$ limit.

## Site Selection and Site Characteristics

For each state, sites were selected on the basis of geographic location, topography, roadway geometric characteristics, and observer safety (Table 1). Sites were generally located on roadway sections that had little or no gradient or curvature, except two sites in New Mexico were not closer than $1 / 2 \mathrm{mi}$ to the nearest interchange. Sites were located on each of Virginia's five rural Interstate highways and were distributed to represent the state's range of topography. In neighboring Maryland, one site on I-95 was selected to match Virginia's I-95 site, and an I-70 site was matched to the more rural nature of Virginia's sites on I-64, I-81, and I-85. Four sites in New Mexico were chosen in the vicinity of Albuquerque on I-25 and I-40, with one urban and one rural site located on each Interstate.

## Data Collection

Procedures used for data collection were similar in all three states. In each state, the speed of free-flowing vehicles was measured using nondetectable K-band radar mounted in vehicles parked either on an overpass above the travel lanes (New Mexico rural sites), off the roadway shoulder behind the guardrail, or in the clear zone (urban New Mexico and all Virginia and Maryland sites). Data collectors recorded the speed, vehicle type, travel lane, registration state, and time of day for each observation. Observer vehicles included several minivans, a small passenger car, and a small pickup truck, none of which resembled vehicles used for local and state law enforcement. Radar units had been modified by their manufacturer so that the signal could not be received by commercial radar detectors (5). Observer vehicle locations were as inconspicuous as possible, and measurements were made with radar units aimed downstream at receding vehicles. Radar calibration was checked at the beginning and end of each data collection session, which was during one weekday between 9:00 a.m. and 4:00 p.m. at each site.

In Virginia and Maryland, speeds at each site were initially measured once during each of the two successive weeks before and two successive weeks after July 1, 1988, the date on which Interstate speed limit signs were changed to 65 mph . Speeds were measured for only 1 day at each site during each sub-
sequent data collection period. Each measurement session at a particular site was performed on the same weekday (Tuesday through Thursday) throughout the study in Virginia and Maryland. Observations were made of traffic moving in one direction only. At New Mexico sites, data were collected for 90 min in one direction, then the observer moved and measured traffic speed in the opposite direction for 90 min . In Virginia and Maryland, data collectors maintained a $\log$ of police, emergency service vehicles, and other unusual activities near the sites. This information was later used to separately evaluate observations that may have been influenced by such events. At the New Mexico sites, virtually no police enforcement activities were observed during data collection.

## Sampling Procedure

Sampling was restricted to free-flowing vehicles whose headway (time separation from the previous vehicle in the same lane) was at least 5 sec . Data collectors were directed to always choose the next free-flowing vehicles in any lane following completion of a speed measurement. The protocol did not attempt to systematically sample each vehicle type according to its proportion within the overall population of all vehicles.

## Analysis Procedure

Raw data were corrected for two factors-angle of observation and radar frequency. Observation angle factor adjusts the speed upward to compensate for measured speed that decreases as a function of the cosine of the angle between the observed vehicle's path and the aim of the radar beam. Radar frequency factor accounts for the difference between speeds measured by standard radar compared with nondetectable radar, which reads 1.45 percent higher. The complete correction for observed speed is given by

Speed $=($ observed speed $)$

$$
\begin{equation*}
\div(1.0145 * \text { cosine of observation angle }) \tag{1}
\end{equation*}
$$

In order to ensure that only free-flowing, unconstrained vehicles were analyzed, observations that had been made within 2 min before and after any observed or suspected event that

may have influenced speed (such as presence or passage of a police vehicle, a breakdown, or citizen band radio communications that identified a radar or enforcement operation) were separated from the data base. Data from the remaining vehicles were analyzed in terms of mean speed, standard deviation, selected percentile values, and the frequency distribution of speed for each data group (6). Observations were grouped by state, observation phase, and vehicle type, and summary statistics were calculated for each group.

## RESULTS

## Immediate Effect of $\mathbf{6 5}-\mathrm{mph}$ Speed Limit

Drivers of cars and light trucks in free-flowing traffic in Virginia raised their speeds on the five rural Interstate highways immediately following implementation of the $65-\mathrm{mph}$ speed
limit. As presented in Table 2, the average speed of cars increased 2.8 mph to 65.9 mph . Tractor-trailer speeds did not increase (in fact, they decreased slightly) in Virginia because the new law still restricted them to 55 mph . Mean speeds on the two rural Interstates in Maryland did not increase but rather decreased for all vehicle types (Table 3). Speeds of cars and light trucks in Maryland after July 1 were 4.5 mph lower than those in Virginia.

In Virginia, the standard deviation (a statistical measure of the range of speed data) was virtually unchanged for cars but decreased slightly for light trucks. Coupled with the increase in mean speeds, this result suggests that the entire distribution of speeds shifted upwards for cars and light trucks because most sampled drivers simply drove faster. The 85th-percentile speed, often claimed as the basis for setting speed limits (7), increased 2.9 mph to 70.6 mph for cars. For tractor-trailers, the 85 th-percentile speed was unchanged. The mean speed of

*Light trucks defined as pickups, utility vehicles, vans, and other trucks not exceeding $\mathbf{1 0 , 0 0 0} \mathrm{lbs}$ gross vehicle weight.
cars in Maryland was slightly lower, whereas the standard deviation and 85th-percentile speed remained unchanged after July 1. These measures for light trucks and tractor-trailers in Maryland were moderately lower after July 1.

The reported standard deviations do not represent speed variance because this term has been associated with the likelihood of a crash. Rather, these standard deviations are withingroup measures combined across both free-flowing and constrained vehicles and across all vehicle types. The sampling and data collection methods do not allow estimation of the standard deviation of the population of all vehicles.
The issue of the immediate effect of compliance with the law can be examined through analysis of the mean speed and the percentage exceeding the speed limit. Following the change to a $65-\mathrm{mph}$ speed limit, the mean speed of cars and light trucks in Virginia became more closely aligned with the speed limit. However, the proportions of free-flowing vehicles
exceeding 65 and 70 mph each doubled (Table 2). The proportion of vehicles exceeding 65 and 70 mph in Maryland during this time was unchanged for cars and decreased for other vehicles.

## Longer-Term Effects of the $\mathbf{6 5}$-mph Speed Limit

## Virginia and Maryland

During the first full year following the speed limit increase in Virginia, the mean speed of cars and light trucks on rural Interstate highways increased an additional 1 mph above the initial increase, as shown in Figure 1. Speeds increased 2 to 3 mph by October 1988 and were highest in January 1989 (up 4 mph from their levels just before the speed limit increase),

FIGURE 1 Mean and 85th-percentile speeds on Virginia and Maryland rural Interstates.
but they subsequently decreased slightly for cars. In contrast, neighboring Maryland's car and light truck speeds were slightly lower during the 4th month after Virginia's speed limit increased. Longer-term trends of the percentages of cars and light trucks exceeding 65 and 70 mph paralleled the speed trends in Maryland and Virginia. The proportions of these vehicles exceeding 65 and 70 mph both doubled initially, whereas Virginia experienced a continuing upward trend
(Figure 2). For cars, the proportion exceeding 65 mph increased to a peak of 69.8 percent in January 1989 and remained at nearly 70 percent through April and July 1989. The proportion exceeding 70 mph also increased to a January peak of 30.5 percent, which subsequently leveled off to about 25 percent. Maryland drivers demonstrated no initial increases in the proportion exceeding 65 and 70 mph between June and July 1988. Peak values were observed in January 1989 and by April

free-flow vehicies; non detectable radar
FIGURE 2 Proportion of vehicles exceeding 65 and 70 mph on Virginia and Maryland Interstates.
returned to levels similar to those before Virginia's speed limit increased.

For tractor-trailers, little change occurred during the year in either speed distribution or percentage exceeding 65 and 70 mph in Virginia, whereas in Maryland both showed an increased trend. By July 1989, distributions of tractor-trailer speeds in Virginia and Maryland were nearly identical.

## New Mexico

In New Mexico, the longer-term trend ( 27 months) of freeflowing car and truck speeds on rural Interstate highways posted at 65 mph was gradually upward, with annual peaks evident each December (Table 4). As shown in Figure 3, speeds for cars, light trucks, and tractor-trailers increased

${ }^{*}$ Light trucks defined as pickups, utility vehicles, vans, and other trucks not exceeding $10,000 \mathrm{lbs}$. gross vehicle weight.
during the first 9 months of the $65-\mathrm{mph}$ speed limit but then increased at a slower pace through the last data collection period in June 1989. The mean speed of cars increased approximately 3 mph between April and December 1987 and stabilized at about 67 mph except for winter peaks. The 85thpercentile speeds of cars followed a more accelerated trend, increasing 2 mph in the first 2 months to 69.3 mph , then increasing another 2 mph to 71.2 mph by November 1987, where it remained. Tractor-trailer speeds increased a total of about 2 mph for mean and 85th-percentile speeds. The standard deviation of speed for cars and light trucks varied considerably from 4.3 to 6.1 mph , whereas for trucks a smaller range was observed. However, no apparent correlation existed between speed and standard deviation within each vehicle type.

The proportion of vehicles exceeding 65 and 70 mph on New Mexico rural Interstate highways increased more sharply than did mean and 85 th-percentile speeds (Figure 3). For cars, the proportion exceeding 65 mph doubled over the 27 -month pcriod, first sharply increasing to 64.8 percent by December 1987 and eventually reaching the 65 to 66 percent level of the last 6 months. The proportion exceeding 70 mph increased almost fivefold.

## Urban Interstate Speeds

New Mexico's urban Interstate mean and 85th-percentile speeds increased only slightly, as shown in Figure 4. The mean speed

free-flow vehlcles; non-detectable radar
FIGURE 4 Speeds and proportion of vehicles exceeding 65 and 70 mph on New Mexico urban Interstates.
of cars increased just 0.8 mph and the 85th-percentile speed of cars increased 1.0 mph by June 1989. Tractor-trailer speeds also showed little change during the 27 -month period (Table 5).

The proportion of vehicles exceeding 65 and 70 mph on urban Interstates increased slightly in New Mexico over the study period. Approximately one-third of cars exceeded 65 mph with little change over 27 months. Similarly, slightly more than 1 in 10 cars exceeded 70 mph throughout the study period. The proportion of tractor-trailers traveling in excess of 65 mph fluctuated between a high of almost 30 percent in June 1987 and a low of about 15 percent in February 1989, but was generally about 20 percent. The proportion of those exceeding 70 mph fluctuated between 2.1 and 7.5 percent, but was most often in the range of 3 to 5 percent.

## DISCUSSION

The analysis indicates that the change to a $65-\mathrm{mph}$ speed limit on rural Interstate highways in Virginia and New Mexico was associated with substantial increases in the speeds of vehicles permitted to travel at 65 mph .

Speeds were measured in Maryland and Virginia just before and after the speed limit was raised in Virginia, so the speed increases that occurred in Virginia were clearly related to the change in the speed limit. Furthermore, the speeds of tractortrailers in Virginia, where a speed limit of 55 mph was retained, did not increase.

Both in Virginia and Maryland, tractor-trailers are limited to 55 mph . The mean speed of tractor-trailers increased in

[^2]Maryland to the same level (about 61 mph ) as in Virginia, where tractor-trailer speeds did not change over a 1-year period. One reason may be that a general trend of higher speed among tractor-trailer drivers is emerging because of widespread exposure to $65-\mathrm{mph}$ speed limits in many states (at least 29 states allow 65 mph for heavy trucks), a strong interest in minimizing trip time, and a desire to keep up with car traffic. Continued monitoring of speeds in these and other states may provide additional insight into the causes and consequences of this phenomenon.
The reported standard deviations are for specific vehicle types-free-flowing cars, light trucks, and tractor-trailersand do not represent estimates of the speed variance of the population of all vehicles because of intermixing in the traffic stream. However, the reported standard deviations do support conclusions regarding the range of speeds of each vehicle type sampled, but cannot be used to evaluate the interactions among vehicles.
The consequence of the $65-\mathrm{mph}$ speed limit and higher speeds has been more deaths. For the 38 states that increased speed limits, 15 to 16 percent more fatalities occurred on rural Interstate highways in 1987 than would have been expected had the $55-\mathrm{mph}$ speed limit been retained $(8,9)$. In 1988 , these same 38 states experienced 26 to 29 percent more deaths than they would have if the $55-\mathrm{mph}$ speed limit had been retained (10). The trend in speeds in Virginia and New Mexico has been gradually upward since the initial large speed increases were observed in those states. Speeds are probably increasing in other states that have adopted the $65-\mathrm{mph}$ speed limit. Consequently, the mortality consequences of higher speed limits will continue to increase.

The $65-\mathrm{mph}$ speed limit has not been found to eliminate speeders (i.e., vehicles traveling in excess of the posted speed limit). One effect of changing from the $55-\mathrm{mph}$ speed limit to the $65-\mathrm{mph}$ speed limit on rural Interstate highways has been to reduce the proportion of traffic technically in violation of the speed limit law. However, the new speed limit has greatly increased the number of high-speed vehicles. The number of automobile drivers exceeding 70 mph has increased fivefold in New Mexico and threefold in Virginia. Approximately two-thirds of the cars observed on these rural highways in Virginia and New Mexico exceeded the $65-\mathrm{mph}$ speed limit during the most recent data collection period in each state. The $65-\mathrm{mph}$ speed limit has had only limited success in recasting drivers who were speeding violators on $55-\mathrm{mph}$ roadways as law-abiding drivers. Instead, because average speeds have
increased and, as evidenced by 85th-percentile speeds, the fastest drivers are going even faster, more high-speed violators now exist than when speeds were limited to 55 mph .

## ACKNOWLEDGMENTS

The authors wish to thank the following organizations, whose cooperation was instrumental in planning and conducting this research: The John F. Kennedy Highway Administration and the departments of transportation and police departments of Maryland, New Mexico, and Virginia. The efforts of the data collection teams from the Center for Applied Research, Inc. (Richard Knoblauch and Marsha Nitzburg), and the University of New Mexico (Jerome Hall) are also gratefully acknowledged. Finally, the authors wish to express their highest praise to those individuals who tirelessly prepared the manuscript: Sharon Rasmussen, Lynn Duley, and Gina Pastore. This work was supported by the Insurance Institute for Highway Safety.
