Maintenance of Unpaved Roads in Wet Climates

T. E. JONES AND Y. PROMPRASITH

In 1987, a research project on gravel roads was established in Thailand between the Thailand Office of Accelerated Rural Development (ARD) and the Overseas Unit of the U.K. Transport and Road Research Laboratory (TRRL). The principal objective was to compare the effects of alternative maintenance strategies for unpaved roads in wet regions. The project also studied the relative performances of motor graders and tractor-towed graders for maintaining roads carrying traffic volumes of 50 to 300 vehicles per day. The potential benefits are the optimization of grading frequencies for different levels of traffic. In addition, the opportunity was taken to evaluate the applicability of TRRL prediction models for gravel road deterioration produced from data obtained in dry and temperate regions to roads in wet climates. Preliminary results from the study suggest that tractor-towed graders can achieve similar reductions in roughness to those obtained with the motor grader. Running costs of the tractor-towed grader units are less than half those of the motor graders. If investment and depreciation costs are considered, then the savings in maintenance costs are substantially higher. An additional problem in Thailand is that of maintaining rural roads built in hilly terrain with gradients up to 17 percent. The ARD has investigated methods of reducing the high maintenance costs on such roads and found that the most cost-effective solution was to surface the most vulnerable lengths of road with concrete blocks. After 2 years' trafficking, this treatment has proved to be highly cost-effective, requiring no maintenance despite heavy rainfall.

Over the past 10 to 15 years, the Overseas Unit of the U.K. Transport and Road Research Laboratory (TRRL) has carried out extensive research on unpaved road deterioration and maintenance in several tropical countries. The results of these studies have led to the development of models for predicting the rate of various forms of deterioration and a means of optimizing maintenance strategies (1).

However, the climate in the countries where research was undertaken has been predominantly dry or temperate. There has, therefore, been a need to validate the prediction models in more extreme climates, particularly in countries with annual rainfall above 2000 mm.

In 1987, a collaborative research project was established in Thailand between the TRRL and the Office of Accelerated Rural Development (ARD) of the Ministry of Interior, Thailand. One of the principal aims of the ARD is to provide an all-weather road network in rural areas and to date it has constructed over 19 000 km of gravel roads in some 73 provinces. The ARD is also responsible for the maintenance of these roads and looks to this research study to determine optimum grading frequencies and to evaluate appropriate equipment to achieve reductions in overall maintenance costs. Current progress on this work is reported.

The ARD is also currently undertaking a project to establish the costs and performance of precast concrete block paving. This technique is now well established in Europe and North America but its use as a surfacing for low-cost rural roads is unusual and if successful would provide an alternative maintenance strategy.

The objectives of the ARD/TRRL research study are as follows:

1. To verify prediction models of gravel road deterioration produced from data obtained in dry and temperate regions under extreme conditions of climate. A minimum requirement is that the existing TRRL models are calibrated for wet climates, but probably new prediction models will be developed.
2. To study the relative merits of different maintenance strategies for unpaved roads in wet regions. This project would enable the TRRL to complete its studies on the performance of gravel roads over a wide range of climates. It has already been established that climate significantly influences the rate of deterioration but there is a lack of quantified data available on gravel road performance under very wet conditions.

Thailand provides an excellent environment for this research project. The rural development networks have roads carrying 50 to 400 vehicles per day (vpd), and in specific geographic areas annual rainfall is in the range 1700 to 2400 mm. In addition, there is a well-established road organization responsible for maintenance.

The potential benefits of this research study to the ARD and other organizations are as follows:

1. The study should enable the maintenance organization to determine optimum grading frequencies, which would result in more cost-effective maintenance, reducing overall maintenance costs and enabling additional funds to be spent on upgrading or construction projects. In addition, by quantifying the changes in surface condition, improved maintenance strategies could be obtained.
2. ARD should be able to evaluate the merits of alternative equipment such as tractor-towed graders and drags to reduce maintenance costs on minor roads.
3. The study should enable the ARD to identify the effect of rates of change in surface condition on vehicle operating costs. This would be achieved by developing prediction models based on the field data and incorporating them in the TRRL microcomputer program RTIM2 (2), which evaluates the costs and benefits of different maintenance strategies. This infor-
information would be invaluable to support requests for maintenance funds from Central Government.

LOCATION OF SITES

Two provinces incorporating elements of the ARD road network are included in the research study. These are Hatyai in the southern region, where the study became operational in July 1987, and Nakhon Phanom in the northeast region where monitoring started in April 1988.

In both provinces, there are 32 test sections, each of which is 500 m in length. All test sections are located on existing roads. The average annual rainfall based on 30 years of records is approximately 2400 mm in each province. There are, however, specific differences in traffic volumes and loading and also in the materials available for gravel wearing courses.

At Hatyai, the traffic varies from 50 to 300 vpd with no heavy vehicles using the test roads, whereas at Nakhon Phanom the traffic varies from 25 to 250 vpd with substantial volumes of heavy traffic on one of the test routes. Materials used for gravel wearing courses in the Hatyai region comprise sandstones, volcanic tuffs, laterites, and limestones, whereas in the Nakhon Phanom region the gravels are derived predominantly from red sandstones of the Maha Sarakan formation together with terraced Mae Khong alluvial sandstones and siltstones.

MEASUREMENT OF EXPERIMENTAL VARIABLES

The principal experimental variables measured in the study are as follows:

- Surface roughness,
- Rut depth,
- Traffic volume and loading,
- Climate,
- Gravel loss,
- Operating costs,
- Material properties (measured both in the laboratory and in-situ), and
- Grading frequency.

Because of their geographic locations, the majority of the ARD road networks have large-radii horizontal curves and vertical gradients of less than 2 percent. Therefore, as the road alignment is similar in most cases, alignment was not included as a variable in this research project. The experimental framework used in the study is presented in Table 1.

The basic framework has 24 experimental sections 500 m long. In two provinces, groups of eight test sections have been established on three different roads carrying the traffic levels presented in Table 1. Each road, therefore, includes three levels of maintenance using a towed or motor grader and two nil maintenance sections. The resultant 48 test sections have been supplemented in both provinces by a further group of eight test sections incorporating a different gravel wearing course but utilizing the same range of maintenance strategies and equipment resulting in an overall total of 64 test sections.

Surface Roughness

Measurements of surface roughness were made using vehicle-mounted bump integrators. These units are calibrated every 6 months against the Abay calibration beam (3) over roads in good structural condition but exhibiting a wide spectrum of roughness levels. In the study, three measurements of surface roughness are taken in each traffic lane. Frequency of measurement has been established at monthly intervals and immediately before and after grading operations.

Rut Depth

The maximum rut depth is recorded in each wheeltrack in each lane utilizing a 2-m straight edge and a wedge calibrated in millimeters. Ten measurements are taken in each test sec-

No of sections | 8 | 8 | 8 |

Duplicate sections are maintained either by motor grader or towed-grader
tion at 100-m intervals concurrently with the monthly roughness measurements.

Traffic Volumes

The traffic volumes on each road incorporating the test sections are measured with automatic inductive loop counters. The counters, using loops buried beneath the gravel wearing course, are read manually each day. They also incorporate loggers that store data for periods of up to 6 months and have the facility to back-analyze. The counter readings are augmented by manual classified traffic counts taken at six monthly intervals.

Traffic Loading

Axle load surveys are carried out at 6-month intervals utilizing the TRRL portable weighbridge. Classified traffic counts are taken concurrently with the axle load surveys.

Climate

A volumetric rain gauge and an automatic intensity rainfall recorder are located on each experimental road. The volumetric rain gauges are read manually each morning, whereas the automatic recorders incorporate data cassettes, which are renewed each month for analysis by microcomputer.

Gravel Loss

Gravel loss measurements in terms of remaining thickness of gravel wearing course are taken concurrently with the roughness and rut depth measurements. Additional measurements are taken when carrying out pavement strength evaluations using the dynamic cone penetrometer (DCP) \(4,5\).

Operating Costs

During each maintenance activity, the operating costs of the equipment are monitored, including the motor grader, tractor and towed-grader, compaction equipment, and water tanker. As the study proceeds, data on vehicle operating costs for the traffic using the rural networks will be collected. These data will then be used to evaluate the vehicle operating costs relevant to different maintenance strategies and surface conditions.

Laboratory Testing

At the beginning of the study, samples of gravel wearing course and subgrade were taken from each section and subjected to laboratory tests. The tests included the measurement of abrasion values, an important parameter in terms of gravel wearing course performance.

In Situ Testing of Materials

At six monthly intervals, before and after the rainy season in both provinces, in situ measurements of material strengths are carried out using the DCP.

RESULTS

Data from Hatyai Province now cover a 2-year period, while 12 months' data have been collected from the Nakhon Phanom Province sites. The monitoring period will cover a period of 3 years. The large quantity of data has not yet been fully analyzed, and this chapter summarizes the more important results to date from both sites.

Roughness

All test sections were surface-graded initially to enable measurements of deterioration to start from the same base. The initial roughness levels of the sections were in the range 2800 to 3200 mm/km. The surface roughness measurements on the Hatyai test roads did not reach levels higher than 6000 mm/km during the first 12 months. This result is partly because of the good condition of the roads, including side drainage, before the onset of the study but also because the rainfall was below average. During the second 12-month period at Hatyai, levels of roughness were up to 20 percent higher, while the rainfall was close to the 30-year average.

Another factor influencing the rate of change of roughness is traffic. Although there is an ADT of 290 vpd on one of the roads, the traffic loading is relatively light. This was the reason for identifying a specific road carrying medium and heavy trucks in the Nakhon Phanom region for inclusion in the study.

Generally, both the towed and motor graders reduce surface roughness by about 30 percent to a level of 3500 mm/km, as shown in Figure 1. However, the roads are still in moderately good condition and it remains to be seen whether, as the roads deteriorate, similar reductions in surface roughness can be achieved by both types of equipment.

The final prediction models for estimating changes in roughness will incorporate measurements of the physical properties of the materials including abrasion and plasticity. These two variables must influence the development of roughness, and laboratory tests are being carried out on each material type as the study proceeds.

Rut Depth

The development of rutting on four consecutive sections in Hatyai is shown in Figure 2. The towed grader was used for maintaining these sections and it can be seen that rut depth after grading was reduced to 5 to 7 mm. This is a good standard for an unpaved road; however, each ARD maintenance operation involves the use of water distributor when necessary and always compacted with a roller, which partly accounts for the low levels of rut depth achieved after maintenance had been carried out. Similar results were obtained when the motor
FIGURE 1 Examples of reductions in roughness achieved with motor grader on two trial sections.

FIGURE 2 Examples of reductions in rut depth achieved with different grading frequencies (towed grader).
grader was used. The rut depths reported are the average of 10 measurements in each section remeasured every 6 weeks. On the nil maintained sections, rut depths have not been allowed to develop beyond 80 mm because of the potential danger to traffic. When this level has been reached, the section is graded and the progression of deterioration begins a new cycle.

**Costs of Operating Maintenance Equipment**

One of the objectives of the research is to evaluate the potential saving using the towed grader instead of the motor grader. Table 2 presents the current costs to ARD of the equipment presently used for maintenance.

The costs are much lower than found elsewhere (1). The low cost of investment and depreciation reflects the age of the fleet in which most of the motor graders are 15 years old and some are 22 years old. The low repair and maintenance costs reflect the high standard of expertise in the ARD workshops. It is too early to predict accurately what the running costs of the towed grader in Thailand will be. However, during each maintenance activity detailed records are kept of all expenditure and consumption, particularly of fuel, which is measured accurately with a calibrated pump. Currently, when the maintenance activity involves a towed grader, the costs are less than half that of the same activity when the motor grader is used. The current ARD allocation for maintenance is 12,000 Baht/km or U.S. $500/km.

**Traffic**

Table 3 presents the estimated ADT on the basis of the automatic traffic counter results.

The maximum axle load found during the first survey was 9.1 tonnes, but the average axle loads for trucks using the ARD road are usually between 5 and 6 tonnes. The maximum traffic loading is expected to be not greater than 5,000 standard axles per year for each road. Further surveys are carried out in the wet season to detect any changes in vehicle type, commodities, and axle loads.

**Climate**

The first 12 months' rainfall was below the predicted average of 2300 mm. From May 1987 to April 1988 only 1550 mm was recorded although over 500 mm of rain fell during December 1987. There were some technical problems with the automatic rainfall recorders partly because of high temperature and humidity but they have been resolved. The 1988/1989 rainfall period experienced levels of rainfall nearer the predicted average. Rainfall in 1989/1990 was higher than normal.

**Gravel Loss**

Gravel loss has been measured in each section. The average losses for 1 year are presented in Table 4.

Testing of Materials

All sections were sampled at the start of the project and the tests have been repeated during the study. One of the objectives of these measurements is to identify any changes in the physical properties of the materials as a result of trafficking and climate. The initial laboratory results are presented in Table 5.

In Situ Strength Tests

The effective strength of an unpaved road varies daily because of changes in the moisture content, which is a function of permeability and rainfall. The U.S. Waterway Experimental Station has carried out considerable research on the traffickability of different soils (6). The results showed that if a road has a California bearing ratio (CBR) greater than 12 percent it is capable of supporting 50,000 vehicle passes with tire pressures not greater than 50 N/cm² and axle loads of 8.2 tonnes. The failure criterion for this analysis was a rut depth of 75 mm. Therefore, this level of bearing capacity should be adequate for most of the unpaved ARD rural roads in Thailand where tire pressures and axle loads are likely to be less than the U.S. values. The ARD-specified gravel thickness for new construction is 200 mm for their standard road. Table 6 presents the in situ CBR values on the basis of dynamic cone penetrometer (DCP) tests on the Hatyai sections, which indicate that, on this basis, strengths are adequate. Further measurements were taken during the wet season to detect any changes that may occur, but preliminary analysis indicates that, apart from the top 50 mm, changes of strength within the road are minimal.

INTERLOCKING CONCRETE BLOCK PAVEMENT (ICB)

The maintenance of unpaved roads can, in some circumstances, become uneconomic, even when grading frequency and other maintenance tasks have been correctly optimized. This may be the case, for example, where steep gradients are unavoidable or where particularly weak subgrades require large quantities of imported material to retain an acceptable running surface.

An unpaved road may also be unacceptable when it passes through a large village because of the accelerated deterioration caused by increased traffic movements and the nuisance created by dust in dry weather.

The usual remedy for these problems in the past has been the application of a double surface dressing. However, since 1986 ARD has experimented with interlocking concrete block (ICB) paving as a potentially more cost-effective solution.

The normal criterion used by ARD for PI is that it should be in the range 6-12.
Summary of Benefits

The benefits of ICB pavements compared with bituminous surface treatment are as follows:

1. ICB pavements require minimized capital investment in heavy equipment.
2. ICB pavements can eliminate the importation of expensive raw materials such as asphalt and fuel.
3. Thailand has a surplus of locally produced cement, and ICB pavements provide alternative uses for this material.
4. The discounted costs of an ICB surfacing over 20 years is about one-third less than a double bituminous surface treatment.
5. ICB pavements can be constructed by unskilled laborers under moderate supervision, whereas bituminous pavements need to be constructed by skilled technicians with high levels of supervision.
6. An ICB of 80-mm web thickness can support wheel loads up to 5000 kg under the worst conditions, such as saturated and weak subgrades and poorly drained materials. Tables 7–9 present results from research done by the Engineering and Technology Faculty in Bangkok (7) under varying conditions of soil type and traffic.
7. Lower labor costs through the use of relatively unskilled labor.
8. The pavement surface can be removed and reused elsewhere if required.
10. ICB pavement provides employment opportunities for local villagers who quickly acquire the necessary skills. For ICB surfacing, labor costs are typically 25 percent of the total project cost. For a double bituminous surface treatment, labor costs are typically 2 percent of total project cost, and this labor is imported.

Experience suggests, however, that ICB pavement is unsuitable where traffic speed regularly exceeds 60 km/hr, and also that construction is slower than for a double bituminous surface treatment.

Economic Advantages of ICB Pavement

The economic benefits from substituting an ICB pavement for a double bituminous surface treatment were based on the following assumptions:

1. A reduction in the initial construction cost of U.S. $900/km.
2. A reduction in the average annual maintenance cost of U.S. $470/km.
3. Resealing the bituminous surface every 7 years.

The first ICB pavement constructed in Thailand was near Chiang Mai. It was constructed in 1986 by the villagers under
ARD supervision without the use of heavy equipment. The total length of the 3.5-m-wide pavement is 434 m, and the cost was U.S. $11,100. This is equivalent to U.S. $25,600/km, of which labor costs amounted to U.S. $8,060/km. A summary of the construction cost is presented in Table 10.

### Performance of ICB Pavements

The performance of interconnecting block pavements has been studied and the results are reported in Tables 7–9. ARD currently use a concrete block 80 mm thick, which provides adequate performance when made with 1:2:4 concrete (by volume). Concrete blocks 50, 80, and 100 mm thick were compared when subjected to repeated loading from a four-wheel vehicle with a gross weight of 13,600 kg. The resultant rutting and cracking presented in Tables 7–9 indicate that performance is directly related to the block thickness.

In northern Thailand, the mountainous terrain, high rainfall, and steep gradients of up to 17 percent combine to cause severe erosion of the surface of unpaved roads. The problem is exacerbated by the poor cohesion and low plasticity of the materials available both in situ and within reasonable haul distance. In some cases, road surfaces are damaged further by trucks using chains on their wheels. The erosion problem is shown in Figure 3, whereas a solution is shown in Figure 4, in which a concrete block pavement has been successfully constructed on a road in hilly terrain and with a steep gradient.

Total Cost = 7,600 + 3,498 = 11,098
Equivalent to US $25,578/km

Note: Timber moulds were used only in the first ICB project. Steel moulds are currently used and cost US $3 each.

It is the intended policy of the ARD to continue using this technique to reduce the high cost of maintenance on these roads in this type of terrain.

The ICB pavement can also solve the problem of serious differential settlement of rural roads in swampy areas because of the lower cost of maintenance and the capacity to support heavy loads. The first project constructed in a swampy area was at Petchaburi, Thailand. The total length of the ICB pavement was 1.20 km, and cost U.S. $38,700, or U.S. $32,250/km.

A total of 215,040 blocks and 4,880 kerbs were used in the project. The road has an ADT of over 1,000 vpd including 60 heavy trucks (of 20 to 25 tonnes gross weight) and 980 medium trucks, pick-ups, and cars as shown in Figure 5. During construction, some sections exhibited large ruts caused by the heavy trucks, but after recompaction of the subgrade and subbase and relaying of the concrete blocks the road remains in good condition after 2 years' service as shown in Figure 6.

Construction Method

The method used to construct ICB paving was as follows:

1. ARD manufactured and initially provided timber moulds for the projects. In current projects, steel molds with three-block capacity are used.
2. ARD located the block manufacturing site and stockpile of materials near the construction site to minimize haulage costs.
3. Demonstrations of construction and laying of concrete blocks were given by 10 skilled laborers of the ARD training center.
4. Laborers were organized into groups performing specific tasks. These consisted of
   a. A concrete mixing group of 6 laborers.
b. A concrete pouring group of 20 laborers provided with 55 sets of timber molds, each set with a capacity of six blocks. Each mold set could be used three times a day and the daily total production rate was approximately 1,000 blocks.

5. After pouring, each block was cured for 28 days. Twenty laborers were used to excavate and install concrete kerbs concurrently with the placement of the sand bed. Laborers were then used to lay the blocks, each individual laborer having an output of 10 to 30 m² per day, while four laborers were normally used to fill the joints between blocks with sand. Final treatment was the compaction of the shoulders and the construction of drainage holes.

The manufacturer of kerbs and blocks can be done using either timber or steel molds. ARD uses timber molds for kerbs, which are larger than blocks, because they are lighter than steel, but only steel molds are used for interlocking blocks. Cast-in-place kerbs give the best results in terms of quality and cost. The 1:2:4 concrete mix provides a specified cube strength for the concrete blocks of 240 kg/cm².

In all cases, the ICB paving is laid on a subgrade of at least 6 percent CBR with the natural material being improved to exceed this figure when necessary. A laterite subbase at least 100 mm thick is necessary although the actual thickness provided will be dependent on the predicted wheel loads and ADT. Finally, a sand layer 50 mm thick is provided on which the blocks are laid, as shown in Figure 7.

The joints between the blocks are filled with sand and dry cement proportioned 1:1, which is compacted using vibrating plate compactors to completely fill the joints and to ensure complete interlock and load transfer between adjacent blocks. A completed pavement is shown in Figure 8. Figure 9 shows the current block and mould design, and Figure 10 shows typical construction details.

CONCLUSIONS

The ARD/TRRL collaborative research study demonstrates the use of appropriate equipment for carrying out the surface maintenance of gravel roads. In many developing countries, there is a scarcity of foreign exchange that would be required to purchase new or replacement machinery. It is far more appropriate to use machinery that is not overly complex and can be maintained and repaired using local expertise and materials. The main criteria should be whether the equipment can achieve standards similar to those obtained by the more complex machinery with the same degree of reliability.

The most important finding so far from the study is the potential savings in maintenance costs by using the tractor-

towed grader. If these savings are sustained, then it will afford ARD the opportunity to increase maintenance on the higher trafficked roads to reduce road user costs. Results from this research will also help the ARD to optimize the frequency of grading for roads with different levels of traffic, materials, and climate.

The use of concrete blocks to reduce maintenance costs in specific areas such as steep terrain and swampy ground has been demonstrated to provide a cost-effective alternative maintenance option.
