# Urban Traffic Volume Patterns in Tennessee 

Boris B. Petroff and Anthony P. Kancler, Division of Highway Planning, Bureau of Public Roads

#### Abstract

Fifty-five continuous-count traffic recorders at 51 locations were installed in Tennessee cities since 1954. The recommendations of the Highway Research Board Committee on Urban Volume Characteristics were used as guides for the selection of locations for these recorders. The 1956 data at 30 locations in 13 cities were analyzed in studies for machine counts. Also, 1955 data at 33 locations were used in the analysis for manual counts.

- AN EXTENSIVE PROGRAM of studies of urban traffic volumes was inaugurated in Tennessee in 1954, since which 55 continuous-count traffic recording machines were located on 51 street sections in 23 cities. In the selection of locations for these installations, the state has followed in general the recommendations developed by the Highway Research Board Committee on Urban Volume Characteristics. These committee suggestions as interpreted by code for Tennessee are given in Appendix A. The designations of the urban continuouscount stations according to this classification are given in Appendix B.

Data for one complete year of operations, 1956, were available for 30 locations scattered throughout 13 cities. Table 1 shows the distribution of these stations by the cities. It is noted that these cities vary in population from 514 in Decaturville to over 400,000 in Memphis (Appendix B).

For the purpose of statistical analysis three tabulating cards were developed: No. 21 (Fig. 1) ; No. 31 (Fig. 2) ; and the general card, the code sheet (Fig. 3).

To determine the actual annual average daily number of vehicles (ADT) at a particular point on the road or street would require continuous counting for 365 days. On the other extreme, a qualified person could make an estimate without counting, just from general knowledge of the situation. The latter method usually would not be considered acceptable because of the suspected lack of ac-
curacy. Because the exact determination is seldom possible, it becomes axiomatic that the ADT's are estimates based on sampling, and the cost of obtaining these estimates must be related to their accuracy. The problem, therefore, is to find means of measuring the accuracy of ADT estimates obtained by various methods of sampling traffic volumes. The measures used in the Tennessee studies make use of the configuration of similar patterns of repetition in the mass movement of the people and the concepts of probability of these repetitions.

At this time only a few basic analyses were made to aid in the evaluation of existing procedures of sampling traffic volumes, and to provide essential measures in the development of new trafficcounting schedules. The present, as well as other possible schedules, was presumed to be based on the assumption that a sample weekday count is representative of the average weekday volume of traffic during the month of the sample count. Therefore, this basic assumption was evaluated and the size of the standard error was estimated. The standard error is a measure of the dispersion of all possible estimates which are based on samples of a given size about their averages. Although the mathematics of probability do not require the knowledge of the true values in these studies, the true (or practically true) values are available at the continuous-count recorders and are therefore used as the basis for measurement of

errors of estimates resulting from sampling.

The following procedure for producing ADT estimates in Tennessee was given particular consideration:

First, the sampling error of $24-\mathrm{hr}$ weekday (Monday through Friday) counts, which were distributed throughout all months of the year, was computed for the six stations in Memphis, as shown in Table 2. The mean coefficient of variation of $\pm 5.9$ percent means that when the traffic volume for a $24-\mathrm{hr}$ period on a given weekday was compared with the average 24 -hr weekday traffic during that month at that point, then, based on a normal distribution, it could be expected that approximately two-thirds of such 24 -hr weekday counts would not
differ by more than $\pm 5.9$ percent from the respective monthly means, and 95 percent of such counts should not differ from their respective monthly means by more than twice the value of the coefficient of variation, or $\pm 11.8$ percent. It is noteworthy that similar tests conducted by the Bureau of Public Roads on the 1954 data at 12 stations in St. Louis, Mo., resulted in standard deviation of $\pm 5.4$ percent; and for 1954-1955 data, except the period December through March, at 10 stations in Detroit, Mich., the standard deviation was $\pm 6.3$ percent.
If the truest adjustment ratio of ADT to average weekday of the month (namely, the ratio derived from the same station from which the sample was
taken) were applied to the sample to estimate the ADT, the measure of error in such ADT estimates would still be expressed by the coefficient of variation of $\pm 5.9$ percent. Inasmuch as the mean
ratio value of the various tests based on annual ADT is unity, the coefficient of variation is equal to the standard deviation. The significance of the measure of standard deviation in these cases is prac-

[^1]tically synonymous with that of the coefficient of variation. Thus, this $\pm 5.9$ percent measure of the sampling error is the minimum that can be expected in the distribution of errors in ADT estimates in this particular study. That is, when these estimates are based on adjustment ratios computed in terms of ADT to average weekday of the month from any other source, it generally can be expected that the error in ADT estimates will be greater than the sampling error of the sample.

Next, the $24-\mathrm{hr}$ weekday counts are adjusted to the ADT by application of appropriate factors. These factors are obtained from a group of stations having similar patterns of monthly variations of traffic volumes. They should be in terms of ratios of ADT to the average weekday traffic of the respective months. Because the factors are based on group values, the resulting group mean values are characterized by differences between the individual station data and the group mean data. Thus, factors are another source of error contributing to the error in the ADT estimates.

The material readily available did not permit evaluation of the error in such factors. However, a reasonable approximation was available in terms of the ratios of ADT to the average daily volume for each month for the 30 stations in 13 Tennessee cities. These ratios permitted measurement of monthly variations and comparisons of these variations among stations (Table 1). It is noted that the overwhelming majority of the monthly ratios vary from the respective
means of the 30 stations by $\pm 10$ percent or less, and the standard deviation of these differences is $\pm 5.2$ percent.

By comparison with the spread of seasonal variation usually encountered on rural roads, the extremely narrow range observed in this study and the implications of these observations as regards traffic survey costs were given special attention in the analysis.

Experience with rural traffic counts (1) indicates that when monthly factors fall within the $\pm 10$ percent range of the group mean, the effect of added amount of error to the sampling error of the 24hr sample in the estimates of ADT is very small. Thus, it appeared that single monthly expansion factors that are the means of the 30 stations could be used in Tennessee for the expansion of $24-\mathrm{hr}$ weekday sample counts so that the resulting errors in ADT estimates would not be much larger than that expressed by the standard deviation of $\pm 5.9$ percent. The $x^{2}$ test on these data (standard deviation $\pm 5.2$ percent) showed a probability level between 5 percent and 1 percent, $(0.05>P>0.01)$. Considering "good fit" within the range from 5 percent to 95 percent, the goodness of fit was not quite acceptable. The normal distribution is applicable only when chance forces are in operation. In this instance the normal distribution of the observed values is borderline, indicating the possibility of forces or heterogencous populations causing results not due to chance alone. The computation of $\chi^{2}$ is given in Table 3 and the values are presented graphically in Figure 4. The tend-

Figure 4. Cumulative frequencies of deviation of factors (ratios of ADT to average day of month) from monthly means.
ency for the traffic observations to concentrate bimodally on either side of the mean contributes to the low $\chi^{2}$ probability level.

Three random samples of 6,5 , and 4 stations were taken from the 30 -station data; the respective standard deviations, $S$, were $\pm 5.93, \pm 4.70$, and $\pm 2.53$. The $F$-test related the variance, $S^{2}$, of each of the three random samples to the variance of the 30 -station data and expressed the probability level of the relationship.

The test showed that the 5 - and 6 -station random samples yielded stable results, whereas for the 4 -station random sample the variations are so much greater as to be unreliable. The formula for the $F$-test is:

$$
\begin{equation*}
F=\frac{S_{1}{ }^{2}}{S_{2}{ }^{2}} \tag{1}
\end{equation*}
$$

where
$S_{1}{ }^{2}=$ the larger variance; and
$S_{2}{ }^{2}=$ the smaller variance.

Another test for conformity, the $T$-test, related the significance of the difference in the monthly means of each of the three random samples to the monthly means of the 30 -station data, but here the differences were not significant for all three. The formula for the $T$-test is:

$$
\begin{equation*}
T=\frac{\bar{X}_{1}-\bar{X}_{2}}{S_{\left(\bar{X}_{1}-\bar{x}_{2}\right)}} \tag{2}
\end{equation*}
$$

where

$$
\begin{equation*}
S_{\left(\bar{X}_{1}-\bar{X}_{2}\right)}=\sqrt{\frac{\left(\bar{N}_{1}+N_{2}\right)\left(\sum d_{1}{ }^{2}+\sum d_{2}{ }^{2}\right)}{N_{2} N_{2}\left[\left(N_{1}-1\right)+\left(N_{2}-1\right)\right]}} \tag{3}
\end{equation*}
$$

$\bar{X}_{1}=$ monthly mean of sample having $N_{1}$ observations per month;
$\bar{X}_{2}=$ monthly mean of sample having $N_{2}$ observations per month;
$\Sigma d_{1}{ }^{2}=$ sum of the squares of the deviations of $N_{1}$ observations from the monthly mean; and
$\sum d_{2}{ }^{2}=$ sum of the squares of the deviations of $N_{2}$ observations from the monthly mean.
A $\chi^{2}$ test on each of the three random samples conformed with normal curve requirements. Random samples are not always representative, inasmuch as such samples are subject to the law of chance. In this particular instance, the use of the 4 -station random sample would appear to be the least satisfactory.

It was mentioned previously that the Tennessee 30 -station data could have had a heterogeneous population. The following method was used to divide the original data into population groups having similar characteristics; in this case, pattern conformity:

1. An array of the 30 stations based on their ratio values was set up for each month of the year (Table 4).

TABLE 4
FREQUENCY DISTRIBUTION OF STATIONS BY VALUE OF RATIO OF ADT TO AVERAGE DAY FOR EACH MONTH AND THE LOCATION OF EACH QUARTILE POINT ${ }^{1}$

[^2]2. The median and quartile values for each month were determined.
3. As shown in Table 5, arbitrary values were assigned to the quartile position of each station for each month, thereby setting up a configurative pattern for each station's relationship to all other stations.
4. The stations were grouped according to individual patterns, as follows:

Group I. A relatively small amplitude of deviations from the monthly medians.
Group II. Tending to deviate greatly from the monthly median values for the first 6 months of the year.
Group III. Tending to deviate greatly from the monthly median values for the last 6 months of the year.

Group IV. Having monthly values occurring within the interquartile range for more than 9 months of the year. In a normal distribution the interquartile range is the 50 percent probability level, as contrasted with the standard deviation of 68 percent. In the Tennessee data this range was approximately $\pm 5$ percent and this group consists of 12 of the 30 stations.
Group V. A station having monthly values closest to the monthly mean or median of all stations was selected. Using the monthly mean or median values of this station (No. 519) as a control, all stations having values falling within $\pm 10$ percent of the control values were included in Group V. Although this method does not necessarily sepa-

[^3]rate populations from a heterogeneous group, it does eliminate extreme values and trouble spots which probably should have been originally eliminated for one reason or another.

To test whether Groups I through V belong to significantly different populations, the groups were checked against each other by the use of the $F$ - and $T$ tests. The results showed that Groups I, II, and III were distinct populations; Groups I and IV were not significantly different, inasmuch as their selection was based more or less on the frequency of monthly central tendency. Group IV is a mixed population, but it can be used when the least variance from the mean is desired. Group V is also a mixed population, tending to resemble Groups I and IV ; it serves to eliminate undesirable extreme values due to error or forces incompatible with the remainder of the data. The separate populations can be broken down into subpopulations; however, there is danger in accepting the manifestations of a small group of individual stations which may not be truly representative of the whole population group.

The $\chi^{2}$ test was applied to all five groups with satisfactory results for all except Groups III and V, indicating that these two groups still had heterogeneous populations and could be further divided into more populations.

Another test supplementing the $\chi^{2}$ "goodness of fit" test to the normal curve was also made, namely, Fisher's $g_{1}$ and $g_{2}$ statistics. For each sample, these are based on the first through the fourth moments of the deviations of the observations from the mean of a frequency distribution where the X -axis is the class interval of the monthly value of the ratio of each station's annual ADT to the average day of the month, and the Yaxis is the frequency of occurrence. Just as the first and second moments about the mean are measures of the average deviation from the mean and the standard deviation, respectively, so are the first through the third moments used to ob-
tain a measure of asymmetry $\left(g_{1}\right)$ and the first through the fourth moments a measure of the kurtosis, flatness, and/or peakedness ( $g_{2}$ ) as compared with the normal curve. The statistics $g_{1}$ and $g_{2}$ are calculated from the $k$-statistics, which are in turn derived from the sum of the powers, from the second through the fourth, of the deviations from the mean of a frequency distribution.

$$
\begin{align*}
& g_{1}=\frac{k_{3}}{\sqrt{k_{2}^{3}}}  \tag{4}\\
& g_{2}=\frac{k_{4}}{k_{2}{ }^{2}} \tag{5}
\end{align*}
$$

In converting the values of $g_{1}$ and $g_{2}$ to " $t$ " values, which show the probability levels and significance of the sample in relation to the normal curve, the following formulas were used:

$$
\begin{equation*}
t_{g_{1}}=\frac{g_{1}}{\sqrt{S_{g 2}^{2}}} \tag{6}
\end{equation*}
$$

where

$$
\begin{align*}
& S_{g_{1}}^{2}\left(\text { variance of } g_{1}\right) \\
& \quad=\frac{6 N(N-1)}{(N-2)(N+1)(N+3)} \tag{7}
\end{align*}
$$

and $N$ is the number of observations in samples.

$$
\begin{equation*}
t_{g 2}=\frac{g_{2}}{\sqrt{S_{g^{2}}^{2}}} \tag{8}
\end{equation*}
$$

where

$$
\begin{align*}
& S_{g_{2}}\left(\text { variance of } g_{2}\right) \\
& =\frac{24 N(N-1)^{2}}{(N-3)(N-2)(N+3)(N+5)} \tag{9}
\end{align*}
$$

An interesting sidelight on the value of $g_{2}$ is its use in determining the minimum size of a sample to be taken from a larger sample or population when the value of $g_{2}$ of the larger sample is known. The following formulas are used:

$$
\begin{gather*}
B_{2}=g_{2}+3  \tag{10}\\
n(\text { size of sample })=\frac{B_{2}-1}{4 V^{2}} \tag{11}
\end{gather*}
$$

where $V$ is the desired coefficient of variation for the standard deviation. In the Tennessee 30 -station data, $g_{2}=0.4477$, and assuming the desired coefficient of variation, $V$, of the standard deviation
is also equal to 10 percent, applying Eq. $10, B_{2}=0.4477+3.000=3.4477$; and $n \quad\left(\right.$ size of sample) $=\frac{3.4477-1}{4(0.10)^{2}}=61.2$ months.

Because each station reports for 12 months, the minimum sample required is $\frac{61.2}{12}$ or 5 stations. However, this sample of 61.2 months is a random sample distributed over all stations and not clustered in five stations. This cluster effect has not yet been investigated, but because of its possible effect the number of stations may have to be raised to 6 or 7 .

It has been observed that when the $\chi^{2}$ test for "goodness of fit" showed weakness, the $g_{1}$ and $g_{2}$ tests tended to substantiate this weakness.

The results of the various tests for the selected groups are summarized in Table 6.

The following conclusions were reached regarding the observations on the $30-$ station Tennessee data:

1. The range of deviations of the monthly ratios from the respective means of the 30 urban traffic stations is predominantly $\pm 10$ percent. The standard deviation for the Tennessee urban stations was $\pm 5.2$ percent. Subsequent studies for urban stations in St. Louis, Mo., and Detroit, Mich., showed standard deviations of approximately $\pm 6.0$ percent. It appears that the confidence limits could be set so that a range lower than $\pm 10$ percent could be achieved if populations could be identified in urban areas. These heterogeneous populations can be separated on the basis of parameters showing similar configurative patterns or selected maximum ranges of deviation.
2. The "goodness of fit" tests as applied to the Gaussian or normal curve can be used to detect heterogeneous populations. These tests include the $\chi^{2}$, and Fisher's $g_{1}$ and $g_{2}$ statistics.
3. Samples may be taken from heterogeneous populations, and with the proper statistical safeguards that they are representative of the original population
they will give satisfactory results. The statistical safeguards are the $F$ - and $T$ tests.
4. The 30 stations mean monthly adjustment factors could be satisfactorily used. Furthermore, practically the same factors could be obtained from the data for 6 or 7 stations randomly selected.
5. The tests indicate the possibility of refinements in the accuracy of adjustments for monthly variations. Such refinements would require identification of populations, which is a costly operation. Even if this were accomplished, the study of Nashville described later would indicate that the improvement in the accuracy of estimates of ADT when based on 24-hr weekday samples could hardly be expected to reduce the value of standard deviation by more than 1 percent.

## NASHVILLE AND MEMPHIS STUDIES

From the data of 6 stations located in Nashville, 63 random samples of $24-\mathrm{hr}$ duration were selected (Table 7). These were adjusted to the ADT estimates by application of the 6 stations monthly means of ratios of ADT's to the respective average weekday traffic volumes (Table 8). The differences (errors) of these estimates from their respective true values were expressed by the standard deviation of $\pm 6.7$ percent. Recalling that the sampling error of the 24 -hr samples was measured by the standard deviation of $\pm 5.9$ percent for Memphis, the effect of factorization on the final error is small indeed. Further, to test the practical meaning of the previously discussed significance of the observed $\pm 10$ percent range of variation in the monthly characteristics of the variations among stations, it was assumed that no monthly adjustment ratios were available from Nashville stations. Instead, the monthly mean ratios from the six stations located in Memphis (Table 8) were used for estimating the ADT's in Nashville using the same 63 samples. The standard deviation resulting from this procedure was $\pm 7.2$ percent. The difference between 7.2 percent and 6.7 percent could hardly

$$
\begin{aligned}
& \text { Standard deviation (Nashville) }=S=\frac{\sqrt{\overline{(1(p e r c e n t ~ e r r o r)}}}{N-1}=\frac{\sqrt{2,786.54}}{63-1}= \pm 6.7 \text { percent } \\
& \text { Standard deviation (Memphis) }=S=\frac{\sqrt{\bar{y}(\text { percent error })^{2}}}{N-1}=\frac{\sqrt{3,255.18}}{63-1}= \pm 7.2 \text { percent } \\
& \\
& N=63
\end{aligned}
$$

be considered of practical significance, yet it implies the complete absence of need for Nashville data for the adjustment of samples. At least for this purpose, the six stations in Nashville could be considered unnecessary. Furthermore, the identification of possible different populations, as previously discussed, could not have had any appreciable practical effect on the accuracy of ADT estimates based on $24-\mathrm{hr}$ weekday samples, as the error could not be expected to fall below the $\pm 5.9$ percent standard deviation of sampling.

A comparison of the same $6324-\mathrm{hr}$ weekday sample counts directly with the ADT's disclosed that the differences between the sample traffic volumes and the
respective ADT's were measured by a standard deviation of $\pm 8.7$ percent. Considering that the corresponding minimum possible measure was $\pm 5.9$ percent, and the best results upon factorization (by Nashville factors) was 6.7 percent, a significant conclusion is derived: if on a 68 percent confidence limit, errors of 9 percent or less would be acceptable as satisfactorily accurate, a $24-\mathrm{hr}$ weekday traffic count may be assumed to represent the ADT's. Similar tests on Detroit and St. Louis appear to bear out this conclusion with qualifications, as follows:

1. The months of January, July, August, and December show a high degree of dispersion for the test observations,

hence are not representative months of the year.
2. There are low-volume roads in urban areas which will also show a high degree of dispersion and may not be reliable.
3. The average weekday count is generally higher than the respective annual ADT, the average difference for the year being about +5 percent of the ADT. When seasonal variation is considered, the average range of the $24-\mathrm{hr}$ weekday count is about 95 to 110 percent of the ADT. In Tennessee, because the factors are already available, the adjustments for monthly variations will be made.

## FOUR-HOUR WEEKDAY COUNTS

Manual counts of 4-hr duration on weekdays are also used in Tennessee cities for the purpose of estimating ADT. The evaluation of the conversion of weekday $24-\mathrm{hr}$ counts to estimates of ADT already has been discussed. Utilizing an electronic computer, a population study was made on the 1955 data of 33 urban continuous-count recorders for the purpose of determining and evaluating the procedure for the expansion of these 4-hr samples into estimates of traffic during 24 hr on weekdays.

Table 9 shows the mean expansion

TABLE 9
FACTORS FOR THE EXPANSION OF 4-HR URBAN COUNTS TO 24-HR COUNTS OS WEEKIAYS AND THE EVALUATION OF THE ACCURACY OF THESE FACTORS, TENNESSEE, 1955

[^5]factors, the standard deviation, and the standard errors of the means of the expansion factors by months and by different 4-hr periods of traffic counts; notable are the great similarities of the mean monthly factors and the consistency of the standard deviation for various 4 - hr periods. It is observed, however, that the greatest variations, average standard deviation $\pm 0.71$, occur during the period from 6 to 10 Am , being 15.8 percent of the mean factor of 4.5 . The smallest variation is for the period from 1 to 5 Pm , for which the average standard deviation is $\pm 0.31$ or $\pm 8.3$ percent of the mean factor of 3.75 . These characteristics indicate that these estimates of 24hr weekday volumes are accurate in terms of standard deviations of about $\pm 12$ to 13 percent, which may be considered satisfactory for practical purposes.

## CONCLUSIONS

1. Traffic counts of $24-\mathrm{hr}$ duration on weekdays may be assumed to represent the annual average daily traffic within certain limitations, some of which have been referred to in the St. Louis and Detroit studies. Although previous studies have indicated that this may result in
an overestimate, the error of this assumption is within practical limits of acceptance.
2. Weekday traffic counts of 4-hr duration during the periods 6 to $10 \mathrm{am}, 7$ to $11 \mathrm{am}, 8$ am to noon, 11 am to 3 Pm , noon to 4 PM , and 1 to 5 PM produce satisfactory estimates of $24-\mathrm{hr}$ weekday traffic volumes when expanded by means of monthly average factors of 33 stations.
3. The monthly variations of traffic are very uniform throughout all 30 stations in 13 cities. The predominant majority of the ratios of ADT's to the daily averages by the months at individual stations fall within the $\pm 10$ percent range from their respective means of 30 stations.
Statistical analyses indicate the existence of several statistical populations in the factors of the monthly variations. However, indications were found that if the various populations were identified the possible refinement in accuracy of estimates of ADT's based on $24-\mathrm{hr}$ samples would be too small to be practical.

## APPENDIX A

CODES USED FOR THE DISTRIBUTION AND LOCATION OF CONTINUOUS-COUNT URBAN STATIONS BY CITY CHARACTERISTICS AND STREET CLASSIFICATION
A. Distribution by city characteristics:
I. By dominant economic base (as described on pages 37 and 48 of the 1950 Municipal Yearbook) :
(a) Manufacturing and industrial, including diversified manufacturing, mining, and transportation.
(b) Retail, including diversified retail.
(c) Wholesale.
(d) Resort.
(e) Education.
(f) Government.
(g) Dormitory.
II. By population size ( 1950 census) :
(a) $1,000,000$ and over.
(b) $500,000-1,000,000$.
(c) $250,000-500,000$.
(d) $100,000-250,000$.
(e) $50,000-100,000$.
(f) $25,000-\quad 50,000$.
(g) $10,000-25,000$.
B. Location by street classification:
I. By traffic function:
(a) Major or arterial streets:

1. Radials that are part of primary state highways.
2. Radials that are not part of primary state highways.
3. Crosstowns (or rings) connecting two or more major radials.
(b) Secondary streets:
4. Radials and crosstowns.
5. Local, commercial and industrial.
6. Local, residential.
II. By average over-all speed range in peak period:
(a) $5-15 \mathrm{mph}$.
(b) $15-25 \mathrm{mph}$.
(c) $25-35 \mathrm{mph}$.
(d) $35-45 \mathrm{mph}$.
